The following is the routine method employed by me now at Kasr-el-Ainy Hospital: About 6 p.m. the patient takes a saline purge (though this is not absolutely necessary, as for a long time I discarded it, though, perhaps, it is better not to omit it), and then fasts all night, and the next morning at seven takes half the above mixture; in half an hour's time he takes the other half; he is kept in bed, still fasting, until the bowels act. Should any depression occur after the first half of the drug, the second half is omitted. (This happened in the case of the youngest pigmy, who only took half the dose.) In young boys and feeble, anæmic patients the dose is divided into thirds, and given with twenty-minute intervals. The dose can be repeated every other day. This effects a considerable saving of time necessary for treatment.

As a rule, three to four liquid stools follow, though sometimes only one. Dr. Looss, who examined the stools in the earlier cases for me, told me that in the first stool there are no worms, and that in the first solid stool after the medicine has ceased acting there are also no worms. He found, further, that the worms are expelled alive; this may account for the absence of worms in the solid stools, as the worms may have time to recover and refix themselves.

Occasionally the first administration is not successful, though why I do not know, and again, very occasionally, after one or two negative results a few worms appear. This may be accounted for, in some instances, as Dr. Hermann suggests, by the fact that the worms having entered through the skin just before admission, not having reached the gut until after the lapse of some time, though in one case (which will be referred to again), a few days after an unsuccessful administration some worms were found *in situ* at the *post-mortem* examination.

The earlier cases were examined by Dr. Looss, but later I detailed a student, week by week, during the summer, to examine the stools. Unfortunately, however, owing to stress of work, on several occasions the stools were thrown away unexamined, and so the results are not quite so full as I should liked them to have been.

In forty-four cases it was wholly successful, as one or more further doses of the eucalyptus mixture yielded no more worms; in some, also, one or more doses of thymol were given with the same object and the same result. In twenty-one cases a single dose was sufficient, a single confirmatory dose of the eucalyptus mixture being given in fifteen, two extra doses in four, and in one, two doses of the mixture and two doses of thymol, with negative result. In four of this series thymol had been previously given before the eucalyptus was tried. In sixteen cases two administrations were sufficient, as confirmatory doses showed. In some of these, as already mentioned, the first dose was unsuccessful, and in several others the second dose expelled more than the first dose. In three cases three doses were necessary, and in four, four doses. One of these latter cases is very instructive. The first dose having expelled no worms, thymol was given twice with a negative result; he was then given eucalyptus five times; the first three of these expelled worms, whilst the last two doses yielded none.

In twenty-six other cases, including the pigmies, it was very efficient, but the patients left hospital before confirmatory doses were given; thus in one case, after seventy-six worms were expelled by the first dose, the patient insisted on going home. So whether these were completely cured or not is uncertain.

In the majority of cases, with the exception of a first administration, if a negative result was once obtained, further dosage expelled no more worms, except in the following instances. Salem Ismail, aged 20: the second dose expelled none, but the third expelled seventy-six and the fourth thirty-three, the fifth being negative. Ibrahim Said, aged 20: the fifth dose expelled none, but the sixth expelled six. Khalil Khalil Said Ahmed, aged 25, who was extremely weak and anæmic, took the eucalyptus mixture on July 22nd, with the result that forty-seven worms appeared; a further dose on the 26th expelled none. He died on the 29th, and twenty-one worms were found *post mortem*. (This case is not included with the successful cases above.)

In twenty-nine other cases the mixture was given in some for diagnosis and in some for treatment. In twenty-three no worms appeared; in five the stools were lost; in another thymol expelled two worms after two doses of eucalyptus had failed.

In three other cases the following results were obtained: In one, after the first dose of eucalyptus mixture, the stools were not examined, but a dose of thymol expelled thirteen worms; a second dose of eucalyptus yielded none. In another the first dose of eucalyptus expelled one worm, then thymol expelled four, and a further dose of eucalyptus five. In the third a dose of eucalyptus and a dose of thymol were unsuccessful, but a second dose of thymol expelled ten, and a dose of eucalyptus seven; a final dose gave a negative result.

The most successful cases were as follows: A first dose expelled 329 worms, a second none. In another the first dose expelled 270, in spite of previous dosage with thymol. In a third the first dose expelled 37, the second 300, the third none. In a fourth case the result of the first administration was not examined, but the second yielded 150, and two further doses none.

That the chloroform is essential is shown by the fact that in three cases where the ova were present chloroform water was given in error instead of chloroform, with a negative result.

Thus the treatment has been employed in 103 instances (the cases in which chloroform water was given being excepted), forty-four of which were entirely successful, in twenty-six efficient, in the other thirty-three either unknown or else negative, being employed in some for diagnosis, or else mixed treatment was adopted. In one, the patient who died, only partially successful.

I think, however, that it is obvious from a consideration of the above results that the treatment is satisfactory with reference to its vermifugal effects. Further, it is not unpleasant for the patient, the long fasting being unnecessary, and the taste of the mixture not offensive. It is cheaper, and repetition being possible three times a week, the stay in hospital is shortened. Lastly, the absence, or rather rareness, of cardiac depression as a result is a good feature. All these facts make it an advance in treatment.

As regards the dosage, if the patient be strong and fairly healthy, I give the larger dose, but if very young (twelve years of age, or so), or very weak, the smaller dose, given in thirds.

Oxyurides are freely expelled by it, and I have used it in one instance to expel a tapeworm, with success.

A CASE OF AINHUM IN ITS EARLIER STAGES.

By F. C. Wellman, M.D.

Benguela, West Africa.

One of the cases of ainhum which I mentioned recently in these columns came to me yesterday and I made a drawing of his foot. He is a young man about twenty years old, and in the best of health. The reason I have been interested in this case is that the process is of recent development, only dating from last wet season. It will be seen from the figure that the

toe has not entirely lost its original contour, and the nail is still intact. He states that the trouble (which is here called "Esola" or "Ombanja") began on the inner and plantar surfaces of the toe, and ascribes it to a fever he had about a year ago. The lesion as yet does not interfere with his walking, running, or carrying, as he is a good messenger and porter. He states that the toe sometimes aches at night.

NOTES FROM ANGOLA.

By F. C. Wellman, M.D.

Corresp. Memb. Am. Soc. Trop. Med.

(*Continued from p.* 328.)

Note XIII.—On the Absence of Certain Diseases from Southern Angola.

It is always a dangerous thing to venture statements as to the absence of any disease from a certain region, as the writer has proved, having had to report the occurrence of one or two affections which he had previously mentioned as probably not existing in his district. Still, the statement may be of value that in the course of somewhat extensive patho-geographical investigations, undertaken in 1896, 1899 and 1903, the following important diseases were not seen or heard of among the natives of this province, viz., typhoid fever, typhus fever, scarlet fever, measles, rubella, diphtheria, erysipelas, rheumatic fever, cholera, yellow fever, plague, Malta fever, pellagra, scurvy, anthrax, glanders, arthritis deformans, and gout.

Note XIV.—"Walking Cases" of Dysentery.

What seems to be amœbic dysentery may, in this part of Africa, be mild, chronic, or recurrent. I have seen cases of whites suffering from "chronic diarrhœa" who, with some effort, were able to be about their work, but in whose fæces might be seen numbers of amœba, morphologically identical with *A. coli*, and even small sloughs. Some months since I saw a fatal case of blackwater fever, supervening on the recrudescence of an old dysentery of this character. Amœbæ, which cannot be told from *A. coli*, are occasionally encountered in the stools of healthy persons here, and accepting (as the writer does) the view that amœbæ are the cause of this type of dysentery, one can understand that these lie ready to invade the intestinal mucosa whenever a favourable occasion presents itself.

Note XV.—An Insect which Preys upon Ticks.

Not long ago I sent to the British Museum an insect which I discovered in the course of some observations on *Ornithodoros moubata*, Murray, and its relation to human spirillosis. The insect is called by the natives "Ochindundu" (the striker), and feeds on the ticks mentioned, catching them and sucking, by means of its powerful piercing proboscis, the blood with which they have filled themselves—much in the same manner as bugs (*A. lectularia*) are hunted by a similar animal, which I remember having heard mentioned in my student days, but the name of which I have unfortunately forgotten, along with more important facts then learned. I have watched the "Ochindundu," and exhibited it to others, in the very act of feeding on the ticks. Its first two pairs of legs are provided with curious paddle-like structures, with which it securely holds the tick while mulcting it of its ill-gotten blood, the insect sitting, as it were, on its long hind pair of legs during this process. When the report on this queer assistant to the tropical sanitarian is received from the British Museum I shall ask the Editors to print it in these columns.

Note XVI.—Concerning the Prognosis of Blackwater Fever.

One occasionally hears from the laity (and even from medical men) such unscientific and meaningless statements in this connection as: "Dr. Blank has never yet lost a case of blackwater fever"; "All my cases recovered"; "Only two cases died out of twenty admitted to the hospital," &c., &c. According to the writer's experience with the disease in this colony there are two classes of patients. The first can endure almost any number of attacks (one hears of men who have suffered fifteen or twenty, or even more), but is unfortunately so small as to almost remain out of the account when making a prognosis. The other class, which includes the vast majority of cases, can usually stand one, or even two attacks, but often go during the third or fourth. Roughly speaking, *the danger increases in geometrical ratio with the number of attacks*. So (at least in this country) in making a prognosis in a given case, or in arranging statistics, it is of the first importance to take account of the number of previous attacks. In fact, I regard mortality statistics in this disease of little or no value without this qualification. The occasional very slight attacks, lasting only a few hours, which are sometimes sandwiched in between the grave attacks, are not a constant enough feature to seriously affect the above calculations. The writer's rule is to invalid home after each of the first two attacks, and to refuse to pass a man to go out after the second.

Note XVII.—A Point in the Life-history of Sarcopsylla Penetrans.

It is well known that the female chigger (*S. penetrans*), when pregnant, burrows into the tissues of her host, and swells up during gestation to a comparatively enormous size. While accurate accounts of the succeeding steps in the metamorphosis have been published, yet in medical literature the descriptions are often vague or erroneous. For instance, we read such statements as these: "The eggs are not deposited while the parasite is in the skin"; "The ova do not leave the body until the parent reaches the soil"; "The female bores into the skin and there deposits her eggs"; "The escaping larvæ give rise to ulcers," &c., &c. During the examination of large numbers of Bantu men, I have made the following observations on this stage in the life-history:—

(1) The eggs are always laid while the chigger is yet imbedded in the flesh of her host.[1]

(2) They never (at least in this climate) hatch into larvæ in the body of the parent.

(3) They are not laid at one time in masses but discreetly, and sometimes at considerable intervals, depending on circumstances. If the chiggers are in the sole of the foot, and the infected person walks about, the eggs may be seen dropping from his feet as he goes, or by pressing gently on the skin near a ripe chigger two or three eggs may be seen to escape one after another. Such eggs readily hatch out. So while it is doubtless a good rule to burn all chiggers removed, yet this has no effect on the usual mode of propagation, and so long as natives go about with infected feet the cycle will go on.

(4) The shell of the parent when dead, and empty of eggs, usually dries up *in situ* and causes no further trouble. Occasionally it may cause irritation, swellings and ulcers, but most of the abscesses, sores, &c., from chiggers come from removing the insects with septic instruments.

(5) The mature ova, if placed in a glass-covered dish containing some dust from the floor, go through the developmental stages common to all fleas, which have often been described. In natural conditions they develop in the dirt and cracks in the floor, and in chigger countries it is therefore important to compel one's native servants to keep their feet clear of chiggers, and to allow no other natives (especially children, who are always infested) in one's quarters.

Note XVIII.—A Clinical Classification of the Tropical Ulcers Seen in West Africa.

Most of the "ulcers" met with in this general region can be fairly grouped under the following heads:—

(1) Tropical phagedæna: (*a*) rapid, (*b*) subacute.
(2) Indolent ulcers.
(3) Malarial sores.

(1) *Phagedæna.*—I recognise two distinct forms of the disease—a severe and a mild—which I have called rapid and subacute phagedæna. Rapid phagedæna is a terrible affection, pursuing a relentless course through skin, soft tissues, and even bone, with frightful rapidity. Joints are disorganised in a few days or even hours, and a limb may become a putrid mass in an almost incredibly short period. It is fortunately rare. I have seen it once beginning on the cheek. Treatment is of no avail and death always results. The attempt of Le Dantec to identify tropical phagedæna with the hospital gangrene of temperate climates can hardly stand in view of the remarkable readiness and thoroughness with which operation wounds heal in the Tropics, and especially among blacks. I have never seen phagedæna or anything resembling it set up in operation wounds, even those made by native doctors with septic instruments. The subacute variety is that usually described in text-books, and is sharply differentiated from the above by its tendency to spontaneously arrest its course and set up granulations. Even in its initial spreading stage it is milder and slower than the preceding (although quite severe enough), and recovery is the rule. It may eventually assume a more or less indolent character.

(2) *Indolent Ulcers.*—The frankly indolent ulcers are often of this type almost from the beginning of their course. They may be active for a few days only at the commencement, and all angry symptoms subside while the sore is no larger than a shilling piece. It is this form which oftenest gives the history of dating from a small spontaneous vesicle (*vide* my note in the

[1] Her different behaviour after artificial removal does not form a real exception to these statements. In such an event she extrudes all her contained eggs at once and dies, but such eggs do not hatch into larvæ. Even if the chigger has completed her gestation and has begun to lay her eggs before her removal, only the most mature eggs in the posterior part of the abdomen will develop.

Journal for April 5th, 1905, p. 118), which I find was mentioned in connection with tropical ulcers by Bechtinger as far back as 1869. They may run on for years. I have seen them completely encircle a limb, although, as a rule, a "bridge" of sound skin is left free even in severe cases. A good many ultimately recover, especially if kept clean.

(3) *Malarial Sores.*—The last type usually appears as a small, definite, generally round, punched-out ulcer which I have called "malarial," because it generally heals quickly under the internal administration and local application of quinine. This peculiarity of the sore was first brought to my notice by Dr. Walter Fisher, of Northern Rhodesia. The name is not exactly fortunate, as the sores are quite possibly not all malarial in origin. This type would probably include the lesions described by F. Plehn, on the Tanga coast and other places. The type is not so constant as the others mentioned, as recent descriptions from different parts of Africa show. The ulcers are generally multiple, and of comparatively trifling importance. A local epidemic of sores in South Angola has been recently reported to me which, judging from a verbal description, also falls under this class. I need hardly say that the different types mentioned in this note may run the one into the other in various cases, and that the classification (which is entirely clinical) is not put forth in a dogmatic spirit, but only as a suggestion to those working on the subject.

(To be continued.)

ON A SPIROCHÆTE FOUND IN YAWS PAPULES.

By F. C. Wellman, M.D.
Benguella, West Africa.

Several weeks ago I sent a communication to the American Society of Tropical Medicine, in the course of which I wrote as follows: "Some time ago while examining a scraping from a yaws papule I was somewhat surprised to see under the $\frac{1}{12}$ several active spirilla-like bodies which, in form and movement, closely resembled *S. obermeieri*. Thinking it to be a case of the parasite of relapsing fever, I thereupon made a prolonged and careful examination of the blood, which, however, contained no spirochætæ. I found the parasites in other papules of the same case.

Only yesterday there reached me the report of the meeting of the British Medical Association at Leicester, which mentions a paper by Castellani,[1] announcing the demonstration of spirochætæ in two cases of yaws in Ceylon. In view of this statement of Castellani's I am emboldened to add the following details from my medical diary to the observation quoted above. I had felt (in view of my failure to find the spirochæte in several subsequent instances) a natural diffidence in submitting the slender evidence of one case; but on reading the paper mentioned I have thought it worth while to call attention to what may be now regarded as a confirmation of Castellani's observation.

From an entry in my diary, dated July 14th, 1905, I extract the following notes: The case was seen during an expedition into Chiyaka district, South Angola. The patient was a girl about twelve years old, who showed a plentiful and characteristic yaws eruption on her face, chest, back, forearms and nates. Having several years ago made an attempt at solving the bacteriological problems connected with yaws, I had at first no thought of examining the secretion from the sores, but unpacked my microscope with the intention of having a look at the girl's blood, as I was in a new district, and such opportunities were rare, owing to the suspicions of the natives. Having gone over two fresh films with no result except a pigmented leucocyte, I was about to replace the instrument when, as my porters were resting, it occurred to me to examine a scraping from one of the papules. On doing so, I at once noticed under the $\frac{1}{12}$ several motile spirilloid bodies which puzzled me, as the natural inference was that I had to do with a case of "tick fever," the parasites of which I had overlooked in my two previous blood examinations. I therefore re-examined the blood with great care, but found no spirochætæ. Making scrapings from two other papules, however, I readily found spirochætæ in both preparations.

I have since carefully examined three more cases of yaws from the same district, with negative results.

I publish this note to obviate any misunderstanding that might arise from the tenor of the paper calling attention to my independent discovery of this organism in yaws papules, which was on its way to America before Castellani's announcement reached me. It is significant that this observation (which has been spoken of as "one of the most important discoveries of recent times, considering the fact that the *Spirochæte palida* has been found, by Schaudinn, in syphilis, and considering the relation said to exist between yaws and syphilis"[2]) should have been almost simultaneously made in two such widely separated countries as Ceylon and West Africa. It is to be hoped that observers in all parts of the tropical world will avail themselves of every opportunity to thoroughly investigate the matter.

I am also publishing a statement similar to the above in America.

SYMMETRICAL PENDENT KELOIDS OF THE EAR.

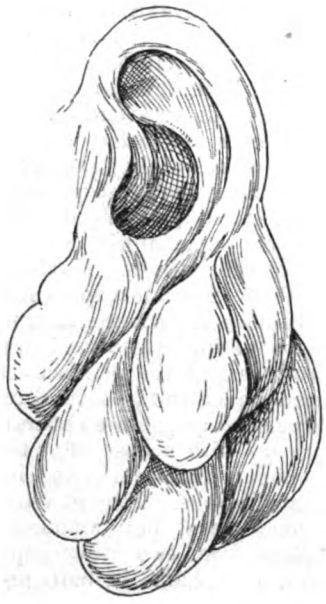
By F. C. Wellman, M.D.
Benguella, West Africa.

I send you a drawing of the ear of a Bantu girl, from which hung a six-lobed keloid, somewhat different in shape and arrangement from any that I had previously seen. As a rule the lobes composing such growths (which are extremely common among the Angola Bantus) are asymmetrical, and often the broadest axis of each lobe is at right angles to its

[1] "On the Presence of *Spirochætæ* in Two Cases of Ulcerated Parangi (Yaws)." Abstract in the *Journal of Tropical Medicine*, August 15th, 1905, p. 253.

[2] *Brit. Med. Journ.*, August 5th, 1905, p. 282.

pedicle. When sessile, and on the trunk, the growths not seldom show a tendency to spread horizontally. In the present case, however, the growth is remarkably regular in outline, the lobes are all ovoid and



nearly uniform in size, their long axes correspond both with each other, and with that of the whole tumour, and the resulting *ensemble* is strikingly suggestive of a small bunch of Madeira grapes.

SMALL-POX INOCULATION IN INDIA.

By Major G. H. Fink, I.M.S., M.R.C.S., L.S.A.(Lond.).

(*Continued from p.* 335.)

I was about to move away when he caught me by the arm, and said: "Here are my children; take and vaccinate them."

I vaccinated his two children then and there, when there was a great rush from all parts of the villages round about to be done, and as fast as I and my superintendent could operate we did so, and thus broke down a barrier which had been set up for years. Are our anti-vaccinationists not very much in the same position to-day?

It is my opinion, therefore, that in the East, among an intelligent people who are willing to reason with you, you must let them have their own way as a matter of experiment, but show them what your duty is, and what the orders of Government are which you are there to carry out, whether right or wrong; and if prevented, the Government should know the reason why their orders are disobeyed. This is clearly our position of the matter, as we cannot possibly do more. We have done all in our power, and the rest is in the hands of the authorities who move the machinery.

In a country such as Sibsagar, where the Assamese are a cleanly people generally, there is very little chance of small-pox epidemics breaking out unless either imported or produced through inoculation. The imported epidemics are through immigrants from congested areas in India coming to enlist in the tea-gardens as coolies, and in a state of poverty and filth in a large number of cases; hence the danger of small-pox in a district depends upon this as one cause and a very common cause, and it is, therefore, very necessary for tea-garden doctors to co-operate with the civil surgeon to so organise the vaccination as to make it impossible for coolies to bring it into a district in Assam. I would, therefore, strongly urge, from the experience I have had, that all coolies be vaccinated before being allowed to enter into Assam, and not after their arrival at the coolie depôts or tea-gardens. This is only fair to the people of Assam, and fair to the medical staff who are short-handed, and fair to all of us who are consumers of tea.

Creative small-pox epidemics, that is, epidemics which occur through inoculation methods, though perhaps not so grave a danger, yet are a danger; hence it is quite right that stringent regulations and laws should be framed to put a stop to this practice for the good of the whole community. It wants knowledge of the people and tact to break down such barriers; but it must never be forgotten that an old custom suddenly broken down, even by reasonable arguments, leaves a sting behind in the case of certain gentlemen of a peculiar temperament, who are the *paterfamilias*, as it were, of the whole community; hence, it is the duty of Government when they frame a rule or law on the subject, to support civil surgeons and to see that the rule is given effect to, and not, as unfortunately does sometimes happen, let those who are charged with this right duty suffer for carrying out an order effectively, which in the case of the Indian medical officer is the receiving of a commission, and he gives his word to obey the orders of the Government, whether that commission designate him as "Surgeon," "Doctor," "Surgeon-Captain," or "Captain."

Misrepresentations there will be, together with plausible arguments on the other side; but these need enquiry into and sifted if we are to be allowed to do our duty as medical officers trained in the schools of England.

I maintain if the Government find that they cannot support their Civil surgeons and Health officers through a difficulty in which these officers have risked even their lives rather than flinch from duty by obedience to an order of superior authority, it is time that a Minister of Health were created for India and the Colonies respectively, who would be responsible for all measures of health to the Prime Minister and the Cabinet, so that laws and regulations will be given effect to properly in matters of disease, and by allowing selected medical officers a seat on the Council of the Viceroy and his Governors and lieutenant-governors who desire to carry out the wishes of the Government, all measures relating to health and disease would receive the best attention possible, and be reported carefully from their scientific aspects through such local councils to the responsible head of the Govern-

ment, and thence through him to the Minister of Health for the information of the Cabinet, and evil practices, which endanger the world, checked. We should by such measures be able more correctly to gauge where the responsibility lies for the carrying out or the cancelment of certain orders when they should be strongly supported, whereas, it is impossible to do so if the wheels of the machinery are allowed to revolve often in opposite directions, as sometimes does occur; while in the multitude of voices, frequently, there is no proper counsel on grave questions of health and disease either given or accepted, and then, when grave epidemics come, the doctors and surgeons have the burden and heat of the day to bear to check it, and very little to encourage them in their work of research.

In dealing with the question of the army of micro-organisms, it is just as important that an organisation should be as complete as in the case of an army of soldiers. Is our medical organisation in every respect what it should be in India? I say most emphatically it is not, although it is a trifle better than it was a few years back.

The reproach often thrown out against the medical department is, that it does not yield a revenue as some of the other departments, hence there is not that interest taken by the Executive in its work. Certainly we are not money-making machines, nor do we seem to be money-taking ones. To obtain that revenue it is necessary to have healthy labour forces, and to obtain a greater revenue for any country at the present time of competition, the labour forces of our Empire must be healthier year by year, and the torch of education in Science must be kept burning for the good of Science. All scientific work of value to commerce should be turned towards Scientific Schools of Education, and Research work encouraged, and such a torch should ever burn in our Empire as was never seen before.

Have we endeavoured to make the medical a revenue-producing machine? If every man were taxed heavily for bringing in dirt and disease we should soon increase our revenue.

To have an army as an efficient fighting machine we require healthy, strong men, well disciplined and drilled in the art of fighting, and for this the people have to pay a large price, and it seems necessary. To have an army for revenue-producing purposes in a healthy way and free from taint we need an army of healthy labour forces at work, working healthily for the good of all. Whose duty is it to see to this? Why, the medical department of the Army, Navy, and the Civil branch of our empire, who must work to save us from reproach, and point out the real evil of inoculation. We can but represent our case, and show the disastrous consequences of the economic machine which shears the medical department year by year, and it rests with the Government to either court disaster, or to help us through our troubles by meeting us at any rate half-way, since we do not flinch from out duty because of the dangers ahead, nor do we discourage people in their worship of any gods if they will only let the medical department do their work according to the light of science, and the testimonies of time and experience which have shown us clearly the history of inoculation among an ancient people, wise in their methods for the times gone by; but which in these days of progress and enlightenment should accept what has been proved by good old Jenner and his followers, who mean to stick to him as the cowherds stuck to their duty bravely at Bristol amid the small-pox which laid low their fellow-men, and who though inoculated in their fingers with the cow-pox from the teats of milch cows, were saved from the terrible ravages of small-pox. No greater experiment for the good of mankind was accidentally produced as at Bristol in the days of Jenner whom we revere now, as much as the cow which is sacred to the Hindoos.

"Journal of Cutaneous Diseases, including Syphilis," October, 1904.

PINTA: PANO BLANCO. P. G. WOOLEY.

Trichophytic diseases are common in Manila. The case is reported of a boy who exhibited slowly spreading pinkish-white patches, irregular in size and shape, on the ankles, dorsa of feet, shins, knees, elbows, hands, wrist, and one on the right shoulder. The patches were roughened, slightly infiltrated and scaling; there was some itching. Scrapings showed mycelial filaments, usually long, ending in a bunch of spores (? penicillium). The condition is identical with pinta, and with the cases of Segram in North Africa, and of Sandwith in Egypt. The presence of sensation and itching exclude leprosy, the colour and odour of the patches insure a correct diagnosis. T. P. B.

"La Tribune Medical," November 4, 1905.

MALTA FEVER IN ALGERIA.

J. Lemaire finds that there is often confusion between this and other prolonged febrile conditions, when there is enlargement of liver and spleen, with anæmia. He considers it of frequent occurrence, having seen thirty cases in five months. In nine cases where 2 to 4 cc. of infected blood were mixed with 250 cc. of pure blood, a pure growth of *Micrococcus melitensis* was obtained. In addition to the tests of Widal and Wright, he injects the expectorations into guinea-pigs, which do not suffer in general health, yet their blood agglutinates the bacillus of Malta fever. T. P. B.

"La Grèce Médicale," January, February, March, 1905.

MALARIA AND HEART DISEASE.

Tsiantaphyllides discusses the connection between the two diseases, and shows that malaria is often the cause of heart disease. Sometimes the cardiac lesion is trivial, at others it is serious, and refuses to yield till active treatment is directed to the malaria. A matter of great importance in practice is that the valvular lesions may be permanent. The chief effects of malaria on the heart fall on the muscular tissue and the valves of the left side, but all parts may be effected. T. P. B.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below :—

50 Copies of four pages, 5/- ;
100 ,, ,, 6/- ;
200 ,, ,, 7/6 ;
50 Copies beyond four up to eight pages, 8/6 ;
100 ,, ,, ,, 11/- ;
200 ,, ,, ,, 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6 ; 100 Copies, 6/6 ; 200 Copies, 7/6.

APPEARING AND DISAPPEARING MEDICAL SCHOOLS.

IN England at the present moment there is a dislocation of medical teaching which is having a serious effect upon many London schools of medicine. In England in the north, the west, and the midlands, universities have within the last few years sprung into existence, and it would seem likely that every large city will soon have its own University. In Scotland there were five universities up to the year 1860, but after the fusion of the two universities in Aberdeen four have been found sufficient to satisfy the insatiable appetite of the Scotch for education. England is now following the example of Scotland and establishing well-equipped universities in the larger centres of population. The people have rebelled against the "universitism" of Oxford and Cambridge; they desire education and instruction in the special sphere they have chosen for their work in life. The University of London first raised the standard of revolt some sixty years ago, but the University of London was, and is, a mere examining board ; and so far as medicine is concerned, an exalted combination of the examining boards of the various corporations of so-called colleges of physicians and surgeons in London, Edinburgh, Glasgow and Dublin. The spirit of municipality has, however, grown rapidly of late, and the glamour of the old-established seats of learning, and of the value of diplomas granted by examining boards has fortunately, or unfortunately it may be, fallen away.

The creation of universities in Sheffield, Leeds, Manchester, Liverpool and Birmingham is responsible for the reduction of the numbers of medical students in the London schools. Some of the schools have sent their pupils elsewhere, and several more are threatening to close their doors.

Increase of expenditure is proving the real cause of these schools' difficulties. When the examining boards demanded that the teachers of anatomy and physiology should be pure anatomists and physiologists the days of the smaller schools were doomed.

The London schools could not afford to pay salaries for eleven or twelve anatomists and physiologists without State aid ; and as that was not forthcoming amalgamation was imperative, involving the disappearance of several of the less endowed schools.

POST-GRADUATE TEACHING.

Post-graduate instruction has become the subject of the hour. Medical men in practice demand it, as proved by the large daily attendance at the Post-Graduate College—the Polyclinic—and at the West London Hospital. Other schools are organising post-graduate teaching, and every London school that has fallen behind in the race is discussing the matter.

St. George's Hospital having dropped student teaching is now asking for a large sum to establish a post-graduate school, but the latest and

perhaps the most important addition to the number of post-graduate schools is that of the

LONDON SCHOOL OF CLINICAL MEDICINE,

in connection with the Seamen's Hospital, Greenwich, London, S.E.

Every one is aware of the public-spirited manner in which the Seamen's Hospital Society came forward in 1899 in the matter of the London School of Tropical Medicine, and provided the means of instruction in tropical diseases at their branch hospital at the Albert Docks; and now the authorities of the Society are about to initiate a post-graduate school at their large hospital at Greenwich. This public-spirited endeavour deserves every encouragement and support. The staff of the hospital in the most unselfish manner have not hesitated, for the benefit of the contemplated clinical school, to forego some of their privileges and to invite eminent physicians and surgeons from other schools to take part in the teaching and clinical work of the school. In the department of medicine we find such well-known names as those of Sir Dyce Duckworth, Professor Hewlett, Dr. Frederick Taylor, Dr. Guthrie Rankin, and Dr. Rose Bradford. On the surgical side the names are of no less consequence: Sir William H. Bennett, Mr. Mayo Robson, Mr. Carless, Mr. William Turner, and Mr. Lawrie McGavin. Mr. Malcolm Morris has charge of the teaching of "Diseases of the Skin," Mr. Cargill "Diseases of the Eye," Dr. St. Clair Thomson "Diseases of the Throat, Nose, and Ear." Practical and tutorial classes are also being organised for all branches of medical instruction. Residential accommodation for post-graduates has not been neglected; and the advantages of a mess and club-room are provided at the hospital itself. The whole scheme has been well thought out and carefully organised; and the liberal lines on which the school has been established brings it home to us that a great public service has been instituted deserving the support of every one who wishes well to the profession of medicine.

EXTRACT FROM THE "EDITORIAL" IN *CLIMATE*, OCTOBER, 1905.

IT is with very sincere regret that we address for the last time the readers of *Climate*, but at the same time we have the great satisfaction of announcing that some provision will be made in the future whereby they may be able to obtain the latest information concerning the progress of tropical hygiene. As will be seen by the correspondence which will be found in another column, the Editors of the *Journal of Tropical Medicine* have generously agreed to devote four issues annually of their valuable paper to the consideration of scientific questions and hygienic subjects, which would be of interest not only to the medical profession, but to the large class of residents in tropical climates, to whom some knowledge of health problems is essential. In the interview with Sir Patrick Manson, which appears on another page, will be found the expression of very strong views as to the necessity of the education in these subjects of all Europeans who are called to labour in tropical climates, and these special issues of the *Journal of Tropical Medicine* will undoubtedly prove to be an important connecting link between the medical experts who are investigating the cause of disease and those who must act upon the advice which they are able to give. As we have often contended, it is of little use for medical men to advocate reform unless they are backed up by the public opinion of the intelligent residents in tropical climates, from whom in some cases the money for the promotion of reforms must be forthcoming, or whose active co-operation, as in the case of governors of Colonies and other high officials, is essential if progress is to be made. Again, missionaries, and those who will have the responsibility in the instruction of native children in the problems affecting the transmission of disease by insects, need it, as Sir Patrick Manson has so well pointed out. But it is almost invidious to single out any classes who should be especially instructed, for the co-operation of all is needed, and the obstinacy of the few who may refuse to adopt hygienic measures may, as is so often the case in other diseases, prove a serious danger to the many.

There will be found enclosed in this issue a special order form for subscription to these special hygienic numbers of the *Journal of Tropical Medicine*, which the publishers have issued, and which contains information as to the method of subscription. We cordially invite our readers to take advantage of this offer.

The cordial support which *Climate* has received from the two British Schools of Tropical Medicine in London and Liverpool has been a matter of great satisfaction, and our hearty thanks are due to Sir Patrick Manson and Major Ronald Ross for much valuable advice and assistance.

Our readers have not been a very large body, but we believe that they are a very influential body, and we greatly value the kind expressions of regret which have reached us from many sides on the announcement of the discontinuance of *Climate*.

To Mr. James Cantlie and Professor Simpson, Editors of the *Journal of Tropical Medicine*, we offer our sincere thanks for their interest in our paper, and we wish them every possible success in continuing the work which *Climate* has begun.

TREATMENT OF BLACKWATER FEVER BY "POTASH."

TO THE EDITORS OF THE "JOURNAL OF TROPICAL MEDICINE."

SIRS,—I was interested in reading a few months back in your Journal a note by Dr. Cameron Blair, W.A.M.S., on the use of potassium salts in the treatment of anæmias generally, and of blackwater fever particularly. I have myself no practical knowledge of the *rôle* of potassium salts in these conditions, but I have observed that "potash" is largely used by the natives of the Lake Chad district when they suffer from "blackwater fever." Their treatment for symptoms which apparently coincide with those of hæmoglobinuric fever in Europeans consists in drinking large quantities of potash water and sucking fresh limes. This seems a rational line of symptomatic treatment, at any rate, but it must be borne in mind that both remedies lie within easy reach of all, and are by no means confined to the treatment of "blackwater fever." I only wish to state facts, any definite conclusions would be premature without further careful investigation.

I am, yours &c.,

ALLAN C. PARSONS,

West Africa Medical Staff, N. Nigeria.

HEREDITY OF ALBINISM.

WE have received the following notice for publication:—

"An important investigation as to the *Heredity of Albinism in Man* is being carried out by Professor Karl Pearson, F.R.S., of University College, London, with the co-operation of Mr. Nettleship (Shottermill, Surrey, England) and Dr. E. Stainer (Physician to the Skin Department, St. Thomas's Hospital), 60, Wimpole Street, London, W. Cases bearing on the subject, *either positively or negatively*, will be very thankfully received by any of those gentlemen. The investigators desire to collect a large series of examples of albinism—complete or incomplete, general or partial—in which the family history of the albino patient can be traced for one, two, three or more generations. The sex and prevalent colour of eyes and hair, in as many of the patient's relations and ancestors as possible, should also be noted, whether any of them were albinotic or not, also all instances of consanguineous marriage. Cases of albinism of the eyes, in persons with congenitally pied skin (most easily recognised amongst dark races) will also be very valuable, even without family history, acquired leucoderma being, of course, excluded."

Towards the elucidation of this interesting subject medical men in the Tropics have ample opportunity of contributing, and it is to be hoped that many will send at least a notification of cases met with in their practice amongst the coloured races.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Monats. f. prakt. Derm.," 1905, p. 88.

INJECTIONS OF CHAULMOOGRA OIL IN LEPROSY.

Tourtoulin began this treatment in 1894, in doses of 5 grammes (1 dram 15 minims). In 1901 he reported that nine cases of leprosy which he had treated with the oil, some subcutaneously, some internally, had, with one exception, all benefited. Eleven cases treated by other observers have all improved: the infiltration diminished, sensation returned, nails grew again. Improvement began to show itself in most cases after the fifth injection. The injections may be painful, and out of 900 injections, four times pulmonary embolism was seen, with difficult breathing, pallor, symptoms not sufficient to prejudice the treatment. The subcutaneous tissue of the forearm or leg is the best place for the injections, which must be continued for years, as the lesions are apt to reappear, though in a milder form, if injections are omitted.

T. P. B.

"Medical News," July 29, 1905.

THE CURE OF LEPROSY.

Dyer has obtained good results only from strychnine, anti-venomous serum, chaulmoogra oil, and chlorate of potash. Ten cases remained free from signs and symptoms from one to seven years, the conclusion being that leprosy is curable, certainly in all the early stages. The essentials of treatment are: (1) Full diet, avoiding only indigestible foods. (2) Hot baths twice a day, with or without soda. (3) The patient needs tonics, febrifuges. Intercurrent or complicating diseases should be watched for. (4) Strychnine is a *sine quâ non* in the treatment. (5) Chaulmoogra oil is best given before meals, in capsules, in hot milk or in milk of magnesia. The initial dose should be three drops, and increased every second or third day. At times it is advisable to give the oil in pill form combined with extract of nux vomica, with tragacanth and soap as excipients. (6) Improvements may be delayed for three or six months or longer. (7) Treatment should be continued when all evidences of the disease have disappeared.

T. P. B.

"Nederlandsch Tydschrift voor Geneeskunde," September 30.

MYIASIS IN THE ARGENTINE. ROORDA SMIT.

In Cordoba infections of wounds are due to *Calliphora anthropophaga*, while in Buenos Ayres *Lucilia hominivorax* is most frequent.

Instrumental interference with wounds is usually disastrous. The most satisfactory treatment is the application of calomel; in the cases of open wounds the powder is dusted on, and a suitable dressing superimposed. In dealing with sinuses of the nose and ear the powder is blown in, and a plug of wool, covered with the drug, inserted.

T. P. B.

"Le Caducée," October 7, 1905.

MOSQUITOES AND HÆMOGLOBINURIA.

M. C. Claude describes four cases seen in Oran, in Algeria.

(1) A married woman, long resident in the district, was attacked with severe gastro-bilious fever, the symptoms being jaundice, vomiting, coma, and three crises of hæmoglobinuria. She had 6 grammes (a drachm and a half) of quinine in hypodermic injections before the first crisis. At this time her husband and sister had severe malaria, without having taken any quinine as a preventive measure.

(2) A married woman, a recent resident, had an access of intermittent fever, which developed into a quartan ague. The symptoms were generalised purpura, pain in the back, two attacks of hæmoglobinuria; and death on the sixth day. No quinine had been taken before the attack. Three to four grammes were administered by the mouth or subcutaneously during the illness. Her husband and sister had characteristic intermittent malaria.

(3) An ex-soldier, an old resident and cachectic, on returning from France was suddenly attacked with fever, having gastro-bilious symptoms, epistaxis, bilious diarrhœa, hæmoglobinuria on the fifth day; death took place on the next day. No quinine had been previously taken; 5 grammes were injected during the illness. At the same time a child of five, in the same house, had a typical attack.

(4) A European girl, aged 19, an old resident, was three days ill with continued fever, epistaxis; a generalised purpuric rash appeared on the sixth day, with hæmoglobinuria; she died on the eighth day. A gramme and a half of quinine was injected. At the same time the rest of the family, four in number, had malaria.

The cases occurred during a severe epidemic of malaria, and the blood was not examined. The conclusion arrived at is that hæmoglobinuria is a paramalarial manifestation, because they appear with similar frequency, at the same times in identical localities.

"Le Caducée," October 21, 1905.

TUBERCULOSIS IN THE FRENCH COLONIES.

Pulmonary Tuberculosis.—Kermorgant states that since New Caledonia was made a penal settlement, the time-expired men have spread tuberculosis amongst the natives, who are decimated by it and leprosy. It is the same in Polynesia, especially at Tahiti.

In Indo-China phthisis is not very prevalent.

In Senegal it is rapidly extending. On the Ivory Coast phthisis and dysentery cause the majority of the deaths. In Dahomey it becomes less common towards the interior, in proportion as there is less contact with Europeans. On the Congo, where it was previously unknown, it is extending rapidly. In Madagascar there is less tuberculosis than in France. It is very common amongst the coolies from Reunion, who stay under observation six months before they are sent to Diego Saurez. At Mayotte it causes a third of the deaths.

In the West Indian Islands the majority of the deaths are due to it, especially amongst the blacks. In Cayenne it carries off a third of the coloured population. In the Colonies tuberculosis is not only extremely common, but also extremely fatal.

Europeans are not more liable to tuberculosis in the Tropics than in Europe, but the disease is much more rapidly fatal. Amongst the semetic races the Arabs are especially vulnerable. Negroes are especially liable to tuberculosis, which is rapidly fatal. The yellow races have only a relative immunity. Half-castes are less resistant than the pure-bred natives. The transport of individuals to a new environment, differing in temperature, in humidity, in prevalent winds and rainy seasons, has a marked influence, and predisposes to bacillary infection, which has an exaggerated virulence.

Occupation, as the fatigues at military service by the natives, soon develops latent weakness. Tuberculosis of the lungs is the scourge of convents. Penal settlements suffer severely; of the convicts in Cayenne, 52·42 deaths per 1,000 are due to tuberculosis, and 110 in New Caledonia. Amongst the ticket-of-leave men it is 43·4 in Cayenne and 104 in New Caledonia. The military garrison have 145·4 out of 1,000 deaths due to tuberculosis in Cayenne, and 228 in New Caledonia.

Climate it only a secondary factor in the production of tuberculosis; the primary cause is neglect of hygiene, and it is in connection with this that prophylactic measures should be taken. In Tahiti alcohol is prohibited, and it should be excluded from West Africa; at all events it should be heavily taxed, and the supply of it as part of the wages of natives should not be allowed.

Tuberculosis and Malaria.—Crespin explains the extension of tubercle in Algeria as due to the relations between the natives and Europeans favouring contagion.

Tuberculosis may develop in persons who have previously suffered from malaria, or the two diseases may appear together. When tuberculosis develops in a patient with chronic malaria, sometimes its progress is very rapid; at other times its progress is arrested, or even entirely stopped.

There is no antagonism between the two diseases.

Surgical Tuberculosis amongst the Arabs. — In Tunis tuberculosis is very common amongst the Arabs, especially in the form of lesions of the bones and joints. It would seem that there is special liability to disease of bone, as shown by the frequency of osteomyelitis, due to hereditary syphilis. Not unfrequently suboccipital caries is seen, starting from the base of the skull, and affecting the neighbouring parts. T. P. B.

NEW CURE FOR DYSENTERY. — Messrs. Allen and Hanbury, Plough Court, London, E.C., have prepared a tincture from the root of a South African plant which has obtained considerable local reputation in the treatment of acute and chronic dysentery in South Africa. Any medical man wishing to test the efficacy of the drug can obtain the preparation from Messrs. Allen and Hanbury.

THE

ANIMAL PARASITES OF MAN

A Handbook for Students and Medical Men

BY

DR. MAX BRAUN

Professor of Zoology and Comparative Anatomy, and Director of the Zoological Museum of the University of Königsberg, Prussia.

THIRD ENLARGED AND IMPROVED EDITION

With 294 Illustrations in the Text

Translated from the German by PAULINE FALCKE

BROUGHT UP TO DATE BY

LOUIS W. SAMBON, M.D. (NAPLES)

Lecturer at the London School of Tropical Medicine; Honorary Member of the Manila Medical Society; Member of the Société de Médicine Tropicale, Paris; The Royal Medical and Chirurgical Society, &c.

AND

FRED V. THEOBALD, M.A.

Vice-Principal and Economic Zoologist to the South-Eastern Agricultural College; President of the Association of Economic Biologists, &c.

Reviews.

THE ANIMAL PARASITES OF MAN.

English-speaking medical men are again indebted to Miss Pauline Falcke for an accurate and excellent translation of a standard German work. To few of us is given the facility to read a foreign language with the expedition necessary in these bustling times, and to even the favoured few who are apt linguists, many lack that intimate knowledge of any foreign language requisite for scientific accuracy. We are therefore beholden to scholars of Miss Pauline Falcke's special attainments for the care and labour bestowed upon translations intended for our instruction and benefit. Messrs. Bale, Sons and Danielsson have time and again risked large sums of money in providing useful translations of medical works, more especially for the benefit of medical men resident in the Tropics, and to them we are deeply indebted, and hope that their efforts are duly appreciated. Encouragement of this useful branch of publication can be shown in one direction only, namely, by purchasing the works intended especially for those engaged in tropical work; and as only the best works in foreign languages are translated, purchasers can have no hesitation in providing themselves with any book Messrs. Bale, Sons and Danielsson place in the market.

The "Animal Parasites of Man," by Max Braun, has no rival; it is the most complete, erudite and accurate book on the subject extant. The investigation of tropical diseases proceeds so rapidly, and new discoveries are so frequent, that even before a book in a foreign language can be translated, however rapidly, the book dealing with them is apt to be behind the times. In the present instance the drawback has been obviated by two masters of the subject in this country, namely, Louis W. Sambon, M.D., and Fred V. Theobald, M.A., who have brought our knowledge of animal parasites in this book up to date.

The introductory chapter on Parasites in General is a liberal education in itself. Plant parasites—phyto-parasites—are not described in this volume; animal parasites—zoo-parasites, are alone dealt with. The parasites are grouped into occasional, permanent and incidental sections. The former terms explain themselves; by incidental parasites are meant those parasites of man that are only rarely met with. The origin and derivation of parasites is interesting reading. The animal parasites of man are classified as:—

A. Protozoa, including the Rhizopoda, Flagellata, Sporozoa, and Infusoria.
B. Platyhelminthes (Fluke-worms), including Trematoda and Cestodes.
C. Nematodes (Thread-worms).
D. Acanthocephala.
E. Hirudinea.
F. Arthropoda—the Arachnoidea, the Myriapoda, and Insecta.

The Culicidæ, or Mosquitoes, are specially and separately dealt with, and other Nematocera, such as Sand-flies, Flies, Gad-flies, Wolf-flies and Tsetse-flies, are fully described.

No fewer than 294 illustrations are portrayed with admirable and teaching distinctness. The text and printing are clear, the paper good, and the whole a handsome volume, creditable alike to the translator and publishers.

The animal parasites of man are found nowadays to play so important a part in disease and in public health generally, especially in tropical countries, that no English-speaking medical practitioner in warm climates can afford to be without Braun's work close at hand.

New Drugs, &c.

The Valley Chemical Company, Danbury, Connecticut, U.S.A., have sent us specimens of Apetal, a stomachic tonic; Thialim, a laxative salt of lithia; Prunol, a stimulating expectorant; Taroena, the Hawaiian Health Food.

"Allenbury's" Teat.—Messrs. Allen and Hanbury, of Bethnal Green, London, E., have added an improvement to the teat of their well-known "Feeder." The teat is so fixed that it is well-nigh impossible for the child to pull it off.

Cyllin as a Disinfectant. — According to researches made by E. Klein, M.D., F.R.S., Cyllin prepared by Jeyes' Sanitary Compounds Company, 64, Cannon Street, London, is fifteen times more efficient than carbolic acid when tested against a vigorous culture of glanders.

COLONIAL CIVIL SERVICE.

Dr. G. Carnana Scicluna, Medical Officer of Health, Malta, has been promoted to the office of Chief Government Medical Officer and Superintendent of Public Health on probation for one year in place of Lieutenant-Colonel R. P. Samut, M.R.C.S., who has retired. Dr. Scicluna has also been made a member of the Executive Council and an official member of the Council of Government.

Dr. J. C. Franklin is acting as Senior Medical Officer of the Gambia during the absence of Dr. R. M. Forde, who has arrived in England.

Lisbon International Medical Congress.—The arrangements for the Congress to be held at Lisbon, in April, 1906, are now well under way. The Congress commences on April 19th and continues until the 26th, and specially arranged excursions are being advertised from London and Liverpool. Those intending to avail themselves of the privilege offered should communicate with the Travel Bureau, 29, Cockspur Street, Charing Cross, London, S.W.

THE STRAITS AND FEDERATED MALAY STATES GOVERNMENT MEDICAL SCHOOL.

Syllabus.

Patron:

His Excellency Sir John Anderson, K.C.M.G.

Council:

The Principal Civil Medical Officer (*President*).
The Secretary for Chinese Affairs (*Vice-President*).
The Honourable The Colonial Treasurer.
The Principal of the School.
The Nominee of the Resident-General: Dr. M. J. Wright, State Surgeon, Perak.
The Nominee of the Straits Branch of the British Medical Association; Dr. Lim Boon Keng, M.B., C.M. (Edin.).
The Honourable Tan Jiak Kim.
Loke Yew, Esquire.
Gan Ngoh Bee, Esquire.

President of the Council and Dean:

D. K. McDowell, C.M.G., Principal Civil Medical Officer.

Principal:

G. D. Freer, M.B.(Lond.), D.P.H.

On receipt of the Governor's reply a meeting of the leading members of the Chinese community was held in the Chinese Protectorate, Singapore, at which the Governor's offer was gratefully accepted and arrangements for the collection of the necessary subscriptions made. Over eighty thousand dollars were finally collected, twenty thousand of which were subscribed in Penang and nine thousand (in one donation) in the Federated Malay States. The Singapore Chinese, headed by the Honourable Tan Jiak Kim (who himself gave $12,000), were by far the largest subscribers.

The condition laid down by the Governor having been amply fulfilled, and the Secretary of State's approval of the scheme having been obtained, a vote was taken in the Legislative Council, and a Bill (Ordinance XV. of 1905) introduced to incorporate the Council of the School.

Under the Ordinance, "It shall be lawful for the Council to grant to such students of the Straits and Federated Malay States Government Medical School as have passed at the school an examination in medicine, surgery, and midwifery (hereinafter called a qualifying examination), diplomas as licentiates of the school."

"Every such qualifying examination shall be held at such times as the Council shall appoint and shall be conducted by a Board of Examiners nominated by the Council, of whom the majority shall be persons not employed as teachers in the school, and the standard required from candidates at any qualifying examination shall be such as sufficiently to guarantee the possession of the knowledge and skill requisite for the practice of medicine, surgery and midwifery."

"It shall be lawful for the Council to cancel any diploma granted under this Ordinance if the holder thereof shall at any time be convicted of any heinous offence or shall be guilty of infamous conduct in any professional respect."

"Every holder of a diploma as a licentiate of the School shall be entitled to be registered under 'The Medical Registration Ordinance, 1905,' or any other Ordinance for the time being in force for the registration of medical practitioners in the Colony and to practise medicine, surgery, and midwifery accordingly."

"It shall also be lawful for the Council to issue certificates of proficiency as hospital assistants or nurses to such students as shall have completed to the satisfaction of the Principal of the School such a course of instruction as may be approved by the Council."

"Semaine Médicale," September 10, 1905.

MALARIA SIMULATING ACUTE PERITONITIS. M. GILLOT.

The symptoms of this larval form of malaria are abdominal dilatation and pain, vomiting, small pulse, &c. The symptoms may occur at the invasion, or during the progress of a malarial attack, also during intermittent or remittent fevers, and as complications in other diseases. The diagnosis depends on the absence or presence of a malarial parasite from the blood, and the result of the administration of quinine, though the parasite may be absent in pernicious attacks, and in patients previously treated with quinine. Typhoid is diagnosed by Widal's reaction, and also by the blood count, which, in malaria, shows slight increase of leucocytes, whereas it is conspicuous when suppuration is present. T. P. B.

"Le Caducée," November 4, 1905.

TRAUMATIC RUPTURE OF MALARIAL SPLEEN: RECOVERY.

A soldier, aged 20, six months resident in Mostaganem, had been twice treated for malaria, with enlargement of spleen.

At two in the afternoon he was hit over the spleen with a revolver in its case. He felt severe pain at the time and he quickly collapsed; there were no other symptoms.

When seen in hospital, at ten in the evening, he was very pale, the splenic area was painful, the abdomen distended and tender, so that the patient laid on his right side. When in this attitude the more dependent part was absolutely dull. The relative dulness extended to the middle line, there was diminished resonance in the hypogastric area as far as the umbilicus, the left side of the abdomen was resonant. The spleen dulness was notably increased.

He complained of pain on the left side of the neck, which prevented him turning his head, there was tenderness on pressure behind the sternomastoid, apparently corresponding to the course of the phrenic nerve. No pulse could be felt in any artery, but only a tremor in the carotids.

On admission 200 cc. of a 1 per cent. gelatine serum and 10 cc. antitetanic serum were injected.

At half-past eleven the patient had improved, the pulse could be felt: 150 cc. of gelatine serum was injected. During the night the patient vomited twice, and slept for an hour.

Next morning the pulse was 110, soft, but regular; the temperature was 35·6° C., and 38.4° C. in the evening. He could turn on to his back, when the sides of the abdomen were found to be dull, especially the right. The pain in the neck was less.

The dulness, pain, and distension of the abdomen lessened; the pain over the spleen continued. The temperature was raised, reaching its highest point, 39·4° C. on the fourth day, and oscillated between 37° C. in the morning and 38° C. at night, finally remaining normal on the nineteenth day.

REPORT ON THE DENGUE EPIDEMIC IN BRISBANE IN 1905.

At the meeting of the Queensland Branch of the British Medical Association, held on April 7th, a Committee, consisting of the President (Dr. Robertson), and Drs. Thomson, Love, Turner, and Wield, were appointed to draw up a report on the epidemic of dengue fever.

Dengue appears to be endemic in the Eastern Tropics. In the summer of 1897-8 an epidemic of the disease occurred throughout the coastal district of Queensland, and in Brisbane attacked a very large proportion of the population.

In the summer of 1905 Brisbane has suffered from a second epidemic, which has also been wide-spread in the State from the extreme north to its southern boundary, and extending also westward to the railway termini. The differences between this and the former epidemic are relatively small, in the main the symptoms are identical, the chief differences being in the relative frequency of certain symptoms, such as the rash, the gastro-intestinal symptoms, &c.

The epidemic commenced towards the end of December, and disappeared in June, lasting barely six months.

Origin and Mode of Spread.—There appears to be no room to doubt that the epidemic was imported from the north. It is undoubtedly highly infectious, but clinical observation does not enable us to form any definite opinion as to the mode in which the infection is conveyed from person to person. In some respects the spread of the disease suggests some peculiarity in the method of propagation differing from that of the well-known diseases, influenza, scarlet fever, measles, &c. It appeared to spread particularly to contiguous houses, whole streets being attacked *seriatim*.

One observation appears to have some bearing on the method of propagation. That is, the medical men have, in many instances, appeared immune to the disease, although exposed to it daily, indeed hourly, until cases appeared in their own households, when they fell victims, being usually among the last members of the households to be attacked.

Similar facts have been reported as to employees in city warehouses.

Earliest Cases.

The earliest case reported to us occurred on November 24th, on the outskirts of the Spring Hill district, and another on December 2nd by the same observer in Swan Hill district. These appear to have been isolated cases; the first outbreak in an epidemic form occurred in the Spring Hill district near the end of December, The disease raged there throughout the month of January, while only a few isolated cases were reported from other districts, until early in February, when it appears to have established itself in fresh centres, and soon prevailed universally, both in the city and suburbs. In the appendix will be found further particulars.

Extent of the Epidemic.

No other epidemic disease attacks such a large proportion of the population. Among the medical profession the impression prevails that it is not an exaggeration to estimate that more than three-fourths of the population have been attacked. When the disease has entered a house, in the large majority of instances all the inmates are attacked sooner or later; it was the exception for one or two to escape, though this occurred sometimes.

From the records given in the appendix as to the prevalence of the epidemic among the Civil Service, employees of several large business firms, and others, it appears that the incidence of the disease in these instances was from about 80 to 90 per cent. These figures probably do not include some of the mildest attacks, as in most instances they refer only to those who were absent from duty. In a suburban return (Belmont) the proportion is lower, about 70 per cent.

Of thirty-three married men attacked in the Defence Force, in twenty-five instances their wives also had the disease, and of their fifty-nine children, fifty-seven were attacked.

On the Island of St. Helena in Moreton Bay, which is used as a convict station, the majority of the warders who were exposed to infection by visiting town were attacked, but the disease only spread on the island to a small extent. Among ten persons belonging to the families of the staff, who did not leave the island, five were attacked, that is, 50 per cent. But of 195 prisoners only five had the disease—2·5 per cent.

Even isolation in the city gaol had a marked influence on the number of cases, as is shown by the following return :—

Boggo Road Gaol.		No.	Attacked.	Per cent.
Male division.	Warders	12	10	83·3
	Prisoners	155 (average No.)	32	20·6
Female division.	Warders	5	5	100
	Prisoners	40 (average No.)	29	72·5

Incubation Period.

It has been very difficult to gather reliable evidence under this head, owing to the multiplicity of possible sources of infection. The general impression seems to be that the period of incubation is from three to six days. There are good grounds for believing it may be as short as twenty-four hours.

The following cases give more definite information :

Dr. Lockhart Gibson : Dwelling five miles from Brisbane, a quarter of a mile from nearest neighbours. Groom had only two opportunities of contracting dengue within a week of his attack. On Monday, horse-feed brought by a man convalescing from dengue. On Wednesday attended a sports meeting in town. Thursday evening, malaise and fever; sent to hospital next day. Discharged Saturday week, after having had a normal temperature for two days, and on the Monday evening following returned to his situation. On the Wednesday evening the cook noticed to have a temperature. She had had no other opportunity of contracting dengue for fully a week previously. Both cases had fairly severe attacks.

Dr. Faulkner : A woman at a solitary farmhouse ten miles from Toowoomba was suddenly seized with the

the initial rigor of an attack of dengue one evening. Exactly twenty-four hours before, a nurse, who was convalescent from dengue, arrived from Brisbane, and slept in the same room. There had been no cases of dengue previously in the house, and as far as could be ascertained there was no other possible source of infection. Seen a few hours before the arrival of the nurse, she showed no symptoms of dengue.

Dr. Little: A servant girl was away for ten days in the bush. On her return she contracted dengue within forty-eight hours.

Dr. Love: A nurse arrived from Southport, where there were no cases at the time; went to Lady Musgrave Lodge, where there was dengue; left same day to nurse a case and fell ill on the third day after arrival, though there was no dengue in the house she went to.

Dr. Wield: A young woman came from Helidon, where there was no dengue, arriving on Friday at 1 p.m.; stayed at an infected house and developed the disease on Tuesday morning.

Dr. Brockway: Mr. W. and two daughters landed in Brisbane from England on April 4th, and on April 8th they all showed symptoms, somewhat suddenly, of dengue.

Age Incidence.

All ages are attacked. The disease has been observed within a few days of birth. Infants usually contract the disease after the mother, but in one or two instances a baby at the breast was the first in the house to be affected. Occasionally suckling infants lying in bed with their mothers, who are suffering from dengue, escape the disease.

Vigorous adults suffer most during the attack. Those previously in weak health are more liable to prolonged and retarded convalescence.

The aged and infirm usually have the disease mildly, sometimes very mildly. A striking instance of this was furnished by the Diamantina Hospital for Chronic Diseases, which contains a large proportion of old people over seventy, and others debilitated by advanced rheumatism, paralysis, cancer and phthisis. Of these two-thirds took the infection, but there were no deaths and no serious cases (excluding the phthisical patients). The proportion attacked may have been larger than two-thirds, as in many the symptoms were so mild as to be scarcely recognisable. Healthy nurses suffered more severely than the patients. On the other hand, several phthisical patients had their tubercular disease aggravated and death accelerated.

General Sketch of the Symptoms.

Among the thousands of cases that came under observation there have been observed many rare and exceptional symptoms and complications. Lest the enumeration of these induce a false impression, it may be well to give a preliminary sketch of the prominent features of the great bulk of the cases. The onset is usually sudden, the initial rise being attended occasionally by a suffusion of the face, known sometimes as the initial eruption. Suffusion of the eyes with often slight photophobia are the rule at this stage. Sometimes the onset is attended by shivering. The pulse is not as a rule accelerated in proportion to the temperature, and may even be slowed. The initial rise of temperature is attended usually by severe headache, as a rule frontal or post-orbital, which, however, is often slight or absent in children. Severe pains, most marked in the lumbar region, but also affecting the limbs, are present in most adult cases. Anorexia is as a rule complete. The tongue varies; it is often densely furred, but may be clean and moist. In many cases abdominal pain and retching are a marked feature. On the third or fourth day there is a remission of the temperature, which sometimes falls to normal. A terminal rise succeeds the remission in typical cases, and is usually accompanied by marked aggravation of the pain in back and limbs, and increased prostration. The characteristic eruption usually appears after the remission and consists of a punctate roseolous eruption, often evanescent, very variable in its extent, and to some degree in its character, but frequently absent even in well-marked attacks. In young childen, who as a rule suffer less from other symptoms than adults, the rash is more prominent. The temperature usually falls abruptly at about the end of the fifth period of twenty-four hours after the invasion. With the fall all the symptoms ameliorate, but do not disappear for another two or three days, or perhaps longer, the tongue, when furred, often being slow to clean, and the distaste for food often continuing after the patient has improved in other respects. The respiratory system is notably free from implication. Complications and sequelæ are infrequent, though loss of strength and general prostration are often rather severe after an attack, and strength is slowly regained.

Onset.—This is sudden in the great majority of cases, being comprised within a few hours. In some well-authenticated instances it is dramatically sudden, the patient being able to point to the actual minute which separated a consciousness of good health from well-marked sensations of fever, headache, general pains, and prostration. Occasionally the patient complains of slight symptoms—headache, prostration, muscular pains—for one or two days before the initial rise of temperature.

Shivering, rarely amounting to actual rigor, is common during the initial rise of temperature.

Temperature.—The average range of temperature had its highest point between 102° and 103°, in a smaller proportion it reached 104°, and cases with temperature above this point were exceptional.

The duration of the temperature was seldom over five or six days, and the prophecy that the temperature would fall at or soon after the end of the fifth period of twenty-four hours after the onset was seldom falsified, though cases of longer duration were observed. In one typical case the temperature lasted two weeks, and fell by crisis, without any complication to account for its long continuance.

The initial rise of temperature was usually moderate, not over 102°, and was in the majority of cases succeeded by a fall on the third, less often the fourth, day, sometimes to normal. This remission or intermission would last a few hours, and would be succeeded by a terminal rise lasting one or two days, during which the temperature would reach its greatest

height, falling by crisis to the normal soon after the patient had appeared to be at his worst.

Hyperpyrexia.—Temperatures over 105° have been noted, but only in a small minority. For instance, a child, aged 3, with extremely developed universal rash, had for some hours during the night a temperature of over 106°, with a weak running pulse, but recovered. A girl, aged 16, had a temperature of 106° in the mouth at the onset of the attack. A girl, aged 6, had a temperature almost 107° shortly after admission into hospital; it fell rapidly after tepid sponging. Several fatal cases in children had hyperpyrexia.

Pulse.—As a rule the pulse is slow in comparison with what would be expected from the rise in temperature. It is common to have a pulse of 75 to 80 with a temperature of 102° or 103° during the first two or three days. Towards the close of the attack the pulse may be more accelerated. There are exceptional cases in which the pulse is accelerated at the outset, and they usually occur in weakly subjects. Several cases have been observed in which the pulse sank to 44 or 48 during or after the second day, with continued pyrexia.

Headache.—This symptom is present in nearly all adult cases, and is usually severe. Post-orbital or frontal headache is the most common form, but there is sometimes also severe parietal or occipital headache, which may be accompanied by hyperæsthesia of the scalp. The eyeballs may be tender to pressure. In some cases there is pain on movement of the eyes, apparently dependent on affection of the ocular muscles. In this condition the patient endeavours to keep the eyes fixed, as any movement of them causes suffering. One case had diplopia accompanied with pain.

Muscular Pains.—Most adults suffer from severe backache, apparently located in the lumbar muscles. This symptom may be present at the invasion, or may appear later than the headache, and is usually more persistent. Often the patient complains of it bitterly. Less frequently the pain is felt more in the interscapular region. Hyperæsthesia of the skin of the back has been observed. Intercostal and abdominal muscular pains are frequent, and are sometimes the symptoms most complained of. Sometimes these pains are specially referred to the scars of old abdominal operations. In many cases muscular pains are felt in the limbs, especially the calves.

Particular Pains.—These are frequent, more especially in or about the lower ends of the femora. Possibly some of the back pains are of this character. They are certainly not in the joints, and are not at all aggravated by movement, and could not be confused with the pains of acute rheumatism. They consist of a dull aching, more or less severe, the sensation suggesting either affection of the bone-ends or of the deep insertions of the muscles or ligaments.

One medical man had marked hyperæsthesia of the skin around one knee-joint.

Sometimes there are shooting pains in the hands and feet.

The very severe limb pains of "break-bone" character have been observed in this epidemic, but only in comparatively few cases.

Initial Eruption.—In many cases there is a flushing of the face, sometimes blotchy, and sometimes spreading into the neck. It appears in the first twenty-four hours, and soon disappears.

Suffusion of the conjunctivæ, and sometimes evident congestion, are very common at the outset. With this there is often some photophobia, slight in degree. These symptoms are less marked than in measles.

Nasal catarrh has been markedly absent.

Sore throat is sometimes complained of, but on inspection only a moderate degree of congestion is observed.

Some observers have noticed a rash on the soft palate.

Tongue.—The condition of the tongue varies between very wide extremes.

In many cases the tongue is rapidly furred, and on the third day may be as thickly coated as that of a neglected typhoid patient in the third week. The furred tongue may become brownish and rather dry on the dorsum, but a markedly dry tongue has not been observed. In many the tongue remains moist, flabby, perhaps teeth-indented, the fur often looking like a moist coat of whitish or yellowish paint.

On the other hand, many patients retain a clean, moist tongue, according to some observers (the majority), and this condition may be present in severe cases, with a high degree of gastric irritability.

Most patients complain of an objectionable taste, variously described as a "fœtid taste," "bitter metallic taste," or "soapy taste," intensified by taking food.

The furring of the tongue, if present, sometimes remains several days after defervescence, and may be very slow to clean. The objectionable taste may disappear still more slowly. The sensation of flavour, particularly of such things as tea and whiskey, is perverted.

Larynx.—A dusky redness of the larynx, nasal mucous membrane, and nasopharynx is characteristic, and may persist for a week or longer after convalescence.

Salivary Glands.—These are not enlarged, and there is no salivation.

Lymph Glands.—These are not enlarged as a rule, but enlargement of the cervical glands is not uncommon. Sometimes the femoral, inguinal and axillary glands are enlarged. Occasionally the glands most enlarged are tender, but the tenderness is not acute. The enlargement is always discrete, and there is no periglandular thickening nor tenderness.

Liver.—Enlargement of the liver and jaundice were not observed.

Spleen.—No clinically recognised enlargement was observed.

Lungs and Bronchi.—The absence of respiratory complications is a conspicuous feature. Sometimes slight bronchitis appears in those previously disposed towards bronchitic attacks. More than one observer has noticed this to be occasionally associated with rusty sputum not due to pneumonia. In a few cases —not phthisical—hæmoptysis was observed of uncertain origin. An irritable cough, probably laryngeal, was sometimes observed.

Several practitioners and others have noticed a

peculiar odour in the patients' breath. Others note a sour, acid smell, probably of the perspiration, but different from that of rheumatism.

Heart.—No endo- or pericardial affection is observed, though præcordial pain is common. There have been a few cases of threatened or actual heart-failure from affection of the heart-muscles or nerves. Cardiac weakness is sometimes noticeable during convalescence. The condition of the heart should be carefully watched, especially in patients past middle life.

Stomach and Bowels.—Complete anorexia is the rule, and there is consequently considerable loss of weight. A few exceptional cases have continued to take ordinary food through the attack, but anorexia is usual even in slight seizures.

Thirst is not marked as a rule.

Vomiting and retching occur in a considerable proportion of the cases, both as early and late symptoms or throughout the attack, fortunately not in the majority. They are the most troublesome symptoms when they occur, and rapidly reduce the patient to prostration. The retching may be frequently repeated without actual vomiting, the nourishment given being retained and only a little clear liquid being brought up.

Gastric pain appears to be present, sometimes quite distinct from that in the abdominal wall. It is much aggravated by flatulence, and may be very acute. A feeling of oppression in the stomach is perhaps more common than actual pain.

Colicky pain with tenderness resembling appendicitis has been observed.

Constipation is the rule, but some few suffer from diarrhœa with mucous or dysenteric evacuations. One patient developed on the fourth day a severe attack of dysentery which gave great anxiety, and kept him an invalid for two months.

Nervous Symptoms.—Headache is present in almost every case, except in children, in whom it is usually slight or absent.

Insomnia is a common symptom, and is often that most complained of. Children, however, are usually drowsy while the fever lasts, and this may be the case in adults.

Persistent and annoying dreams are complained of by some patients.

Delirium is less than would be expected from the intensity of the fever. Very rarely there is severe delirium. Sometimes there are hallucinations. In children convulsions may come on with the initial rise of temperature (rarely later), especially in those under five years. One infant of ten weeks had fatal convulsions with hyperpyrexia on the fourth day.

Depression varies much in different patients. It is usual after the third or fourth day, and during convalescence.

Mania was observed in two cases; hysteria in several.

The poison of dengue appears to have a special action on the peripheral nerves, and doubtless this is the explanation of the very various pains which are so common, often severe, and occasionally unbearable. That this is so is confirmed by the cases of cutaneous hyperæsthesia. Affection of the motor nerves is seldom observed, but the case of diplopia can hardly be otherwise explained. Among the sequelæ peripheral neuritis is noted, though in but few cases.

Hæmorrhages.—Epistaxis occurs sometimes, more often in children, and may be profuse.

Hæmatemesis has been rarely observed in the present epidemic.

Hæmoptysis has been already noted as occurring in a few instances.

Hæmaturia has been observed once or twice in patients with previously healthy kidneys.

Subconjunctival and retinal hæmorrhages are also of rare occurrence.

Several cases of cerebral hæmorrhage took place during attacks of dengue.

One case had subcutaneous hæmorrhage in one leg, accompanied by effusion of blood into the ankle-joint.

Some degree of increased menstrual loss is the rule, and may amount to menorrhagia. The period is also usually accelerated.

Renal Functions.—Albuminuria is not often observed, but there have been several instances of a fair quantity of albumin appearing during the attack, and disappearing soon after defervescence. In one case it did not disappear for two or three weeks.

In some cases the urine is extremely scanty, high-coloured and loaded with urates.

One case is reported of a non-pregnant woman in whom dengue was accompanied by albuminuria and convulsions. The patient recovered, and the albumin disappeared during convalescence.

Another case was a woman over 80 who had previously suffered from high arterial tension and infrequent pulse without albuminuria, but developed 5 per cent. of albumin with the onset of dengue, the albumin disappearing a few days after defervescence.

Several other similar cases could be quoted, and probably albuminuria occurs more often than is suspected. One case of adolescent albuminuria was apparently cured by an attack of dengue.

Terminal Rash.—This appears on the fourth or fifth day, and is often first observed just before or after the crisis. It may, however, appear earlier. In many cases the rash is slightly developed and evanescent. In this epidemic a large proportion of patients, placed by some at one-half or more, have had no rash. There is, however, some difference of opinion on this point, and some would place this proportion lower. This appears to be due partly to the greater diligence displayed by some in searching for a slight and fugitive rash; partly by their recognising slight appearances, which others would not consider to be distinct eruptions. While no rash has been observed in some severe cases, it has been usually absent in mild cases, except in children, in whom its absence is infrequent.

The usual rash is an eruption of minute red spots, smaller, less raised, and brighter red than that of measles, but considerably larger, more discrete, and not so vividly red as that of scarlet fever. On the whole, it has most resemblance to the eruption of rubella. Its favourite sites are the upper part of the chest, back, extensor aspect of limbs about elbows and knees, and the front of the forearms. In a minority the rash affects the palms and soles as a carmine-pink

suffusion, which is extremely characteristic. More rarely the rash in these parts may be punctiform.

In children the rash is occasionally universal, the face included, and largely confluent, so that, although commencing differently, it comes to resemble a highly developed scarlet fever rash.

In most cases the rash on the palms and soles is extremely itchy, that on other areas is less frequently so. The itching persists after the rash has disappeared for a day or two. If the rash is much developed it is followed by desquamation, which is most marked on the hands and feet. In one child with an extreme rash the desquamation was in flakes, the cuticle separating from the fingers and toes like glove-ends.

In some cases the rash varies from the common form. In a few severe cases there has been a dusky rash of discrete spots widely distributed over the trunk and limbs, lasting several days, and somewhat suggestive of measles.

A scarlatiniform rash has been seen in a few cases by several observers.

An urticarial rash: an eruption of urticarial wheals has replaced the usual rash in one or two cases.

A petechial rash: one case is reported.

(No sporadic cases of measles or scarlet fever have been noticed during this epidemic.)

Relapses and Second Attacks.

An attack of dengue during the previous epidemic had no or very little protective influence in this one.

Though dengue usually runs its course within five or six days, cases have occurred in which fever continued for ten days or more, often with a remission, sometimes with two outbreaks of the rash, and these may be looked on as cases of relapse. In others several days or a week of normal temperature intervene. Between these cases and second attacks no line can be drawn.

Second attacks have occurred at intervals up to three months. As a rule these have been severe, and have followed mild attacks, but the contrary has been observed.

Complications.

Pneumonia and pleurisy are very rare complications; a few cases have been observed.

Parotitis has occurred also in a very few. Orchitis was noticed in several cases.

Ulceration of the mucous membrane of the mouth and gingivitis was occasionally noted; in one case this was followed by fatal tetanus. Superficial ulceration of the fauces is also recorded.

Diarrhœa, sometimes with mucous evacuations, is not very infrequent.

Dysuria occurs now and then, but actual retention is very rare.

Pregnancy in most cases has not aggravated the disease, but there has been a tendency to miscarriages and premature labours. In some of the latter instances the children were still-born. Dengue in the puerperium does not seem to have been specially harmful.

Sequelæ.—Boils and carbuncles have not been very uncommon sequelæ. An itchy vesicular eruption on the fingers and palms of the hands is occasionally troublesome. Two cases had widespread eczema. Women frequently complained of shedding of the hair during convalescence, and cases were noticed in which the hair went rapidly grey.

A special proclivity to X-ray burns was noted in two patients after attacks of dengue. Perfectly similar exposures with the same tubes had been previously well borne by them.

Muscular rheumatism, including backache and inframammary pain, was sometimes persistent.

Three cases of synovitis of the knee are recorded.

Mastitis occurred in two cases; neither suppurated.

Venous thrombosis, sometimes ending in suppuration, was a very rare sequelæ.

One case of gastritis is recorded. Also one of diabetes.

An adult (aged 35) who had previously suffered from slight albuminuria and slight cardiac hypertrophy, suffered from repeated attacks of heart-failure after the subsidence of dengue. He had never had such attacks previously.

Another case had persistent and troublesome palpitations without cardiac lesion.

Keratitis and corneal ulceration occurred both as complications and sequelæ, but fortunately in a very small minority of cases. Dr. Lockhart Gibson reports some interesting cases, which are given in an appendix. Asthenopia was sometimes noted for the first time, or aggravated. In one case optic atrophy, probably from retrobulbar neuritis, supervened.

Neuralgias are not uncommon. Slight symptoms of peripheral neuritis were noted by several observers. Usually numbness was the most prominent symptom, accompanied by some paresis, and perhaps by loss of knee-jerks.

Giddiness was sometimes complained of. Nervous depression and loss of memory sometimes persist after the attack. Loss of memory for words, and a tendency to misplace letters in writing, are recorded by two observers. In one or two cases the nervous depression progresses to melancholia, which subsequently cleared up.

Dengue Complicating Previously Existing Diseases.—In nephritis the quantity of albumin is increased, and in a few uræmia supervenes. But many cases of nephritis go through the disease without apparent harm.

One case of diabetes had fatal coma.

Cases of phthisis often go to the bad after an attack of dengue.

Skin diseases are aggravated; so is previously existent neuritis.

Any ulceration, especially varicose, is apt to spread.

Mortality.

In the return kindly furnished by the Government statistician, which will be found appended to this report, ninety-four cases are reported to have died from dengue in Brisbane, among a mean population of 125,672. The great bulk of the mortality occurred during the months of March and April, during which it considerably swelled the the general mortality. If it be assumed that one-half the population were attacked, this would correspond to a case mortality of 1 in 668; if 75 per cent. were attacked, which is probably under the mark, to a case mortality of 1 in 1,000. The mortality was relatively greater in

females than males. The highest mortality occurred at the extremes of life, those under 5 years of age contributing 37·6 per cent., and those over 60 years 35·5 of the total.

The mortality returns probably give an exaggerated idea of the immediate fatality of the epidemic. The overwhelming majority of those attacked are never in a condition to give rise to any anxiety. Some medical practitioners with large practices have seen no deaths, others only a few. In the Brisbane Hospital, out of 566 cases admitted (and therefore, no doubt, selected as being severe cases) there was only one death.

As a result of enquiries we are indebted to several medical men for particulars regarding the fatal cases occurring in their practices, and adding to these those that came under our own observation, we have collected thirty-five fatal cases, of which one occurred in Toowoomba, eight in Ipswich, and the remainder in Brisbane.

Under Five Years.

Children's Hospital: A child, aged 3, developed hyperpyrexia with some convulsive seizures on the fifth day. The temperature resisted antipyretic measures. Death occurred from heart-failure within twenty-four hours.

Dr. Bancroft: A feeble infant, aged 6 months, was seen with a slight rash, temperature of 101°, and vomiting, and died suddenly on the same day.

Dr. Kerr-Scott: A healthy female infant of 10 weeks took convulsions with hyperpyrexia on the fourth day, and died in six hours.

A female infant of 10 months developed bronchitis on the sixth day. Sudden and unexpected death from syncope on the ninth day.

Dr. Brockway: An infant of 5 days developed a copious rash, refused the breast, and died.

Dr. Turner: A boy, aged 2, was seen about the fifth day with a slight rash and great prostration. Died from heart-failure next morning.

A girl, aged 4, who had suffered many months from chronic lead poisoning, but had improved, died of long-continued convulsions, which were probably uræmic. They came on a few days after temperature had fallen.

Dr. Halford: Female twins, aged 11 months, both delicate from birth, bottle-reared. Had been subject to gastro-intestinal disturbances, and contracted dengue about one month before death from exhaustion. Both cases were complicated by staphylomatous ulceration of corneæ.

Dr. Cameron (Ipswich): Girl, aged 4, suddenly seized with fever, restlessness, pains all over. Next morning convulsions, which lasted until death, twenty-four hours after onset. Mother was in bed with dengue, and father had had it a few days before, so that it was inferred that the child was suffering from the same. It was apparently healthy, but had had convulsions on two previous occasions.

Male infant, aged 8 days. Mother suffering from dengue when confined. Baby healthy at birth, suddenly became febrile and died after a few hours' convulsions. Probably dengue.

Male infant, aged 11 months. Severe attack, on third day repeated convulsions, high fever, and death.

Infant of 17 months. Fatal convulsions on second day.

Between Five and Sixty Years.

Dr. Kerr Scott: Female, aged 29. Advanced phthisis, dengue, and exhaustion.

Dr. Love: A stout man, aged 55, who had previous symptoms of cardiac weakness, died of sudden heart-failure shortly after the subsidence of dengue.

A child, aged 8, had persistent vomiting after dengue, and died of exhaustion.

Dr. Thomson: A lad who had been a cellarman, and drank freely, died of cerebral hæmorrhage within forty-eight hours after getting out of bed.

Dr. Hawkes: Woman, aged 28, two and a half months pregnant, had a severe attack of dengue, temperature 103° to 104°, within twenty-four hours had uterine hæmorrhage. When seen on third day had offensive discharge, uterus tender and soft. On fourth day uterus emptied by finger and soft blunt curette. Uterus flabby and almost impalpable, very little hæmorrhage. Did well for three days and then died with symptoms of pulmonary embolism within a few minutes.

Woman, aged 53, who had probably had a fatty heart for some years, on third day had cardiac pain, dyspnœa, acute dilation of the stomach, and died in a few hours.

Dr. Turner: A woman, aged 46, who had been under treatment for some months for anæmia, with subcutaneous hæmorrhages, complicated by hæmaturia at first, and later by albuminuria without blood, had suppression of urine and fatal convulsions on second day after temperature had fallen to normal.

Dr. Halford: Married woman, aged 42, had on fourth day severe abdominal pain and collapse. When seen on the fifth day nothing could be found to account for symptoms; died soon after.

Man, aged 24, died of phthisis accelerated by dengue.

Dr. Cameron (Ipswich): Man, between 30 and 40, had a moderately severe attack, keeping him in bed a week. Two days after getting up had difficulty in walking, inco-ordination of legs, loss of knee-jerks, no impairment of sensation. He was not seen again, but died a week later.

A very stout woman, aged 50, had severe dengue, with persistent vomiting and diarrhœa. Died of heart-failure; probably heart was fatty.

Dr. Faulkner (Toowoomba): Man, aged 35, a baker, had been much overworked owing to illness of employees. Dengue with extremely severe vomiting and diarrhœa, aggravated by injudicious diet; died of exhaustion on the thirteenth or fourteenth day, though his temperature had come down.

Over Sixty Years.

Dr. Kerr-Scott: A man, aged 68, who had suffered from diabetes for several years, became extremely weak and died on the fifth day.

A woman, aged 80, had dengue, complicated by nephritis on the fourth day. Died on the seventh day from heart-failure after almost complete suppression for twenty-four hours.

Dr. Bancroft: A feeble old woman, aged 70, died

from cerebral hæmorrhage; had had an attack some years previously.

A feeble old man, aged 70, subject to fainting attacks, died after a week's illness.

A case, aged 75, suffering from cardiac disease, died of syncope.

Dr. Thomson: A feeble old woman who had had a weak heart, died suddenly.

Dr. Hawkes: Female, aged 78, had had mitral disease with enlarged, degenerated heart. On fourth day had an anginal attack, followed by a fatal seizure a few hours later. Urine albuminous before the dengue for some time.

Dr. Halford: Woman, aged 75, subject to chronic bronchitis and dilation of right heart; gradually developed broncho-pneumonia, and died about three weeks after contracting the infection.

Dr. Cameron (Ipswich): Female, aged 74, severe attack, persistent, uncontrollable vomiting, then diarrhœa.

Male, aged 63, healthy; dengue and diarrhœa, finally passing almost unmixed blood; ill two weeks.

Some General Remarks on Dengue.

In its occurence in wide epidemics, its rapid diffusion, the large proportion of the population attacked, and very closely in its symptoms, and their comparatively short duration in most cases, dengue closely resembles influenza.

The usually sudden, sometimes instantaneous onset, the severe headache, backache and limb pains, the pyrexial symptoms, and many of the complications and sequelæ are common to both. The rash of dengue, which is, however, not a constant symptom, is sufficiently distinctive, but of even more importance is the almost invariable absence of catarrhal symptoms of the respiratory tract, and the extreme rarity of pulmonary complications.

At the outset of an epidemic of dengue, it is very commonly mistaken for influenza, and often it is not until the practitioner has seen several cases with a rash that he revises his opinion. In future, supposed outbreaks of influenza occurring in Queensland during the hot season will be rightly regarded with suspicion.

The initial symptoms of yellow fever, a disease fortunately unknown in this part of the world, closely resemble those of dengue as far as the stage of remission. In dengue, too, there is a comparatively slight but real tendency to hæmorrhages of various kinds, including hæmatemesis.

In Brisbane the symptoms of dengue have been observed free from any complication with malaria. We understand that in the North of Queensland some confusion has occurred from the intercurrence of the two diseases.

Judging from the experience of our two epidemics, and from those recorded elsewhere, dengue, like other infectious fevers, appears to vary somewhat in type. The proportion of severe cases, and the relative frequency of many of the symptoms and complications are not always the same, but dengue appears to be for all that a disease as distinctive, and as easily diagnosed when it prevails in the epidemic form, as the other exanthemata.

Appendix I.

Statistical Office, Brisbane,
June 21st, 1905.

Sir,—In accordance with your personal request, I have much pleasure in quoting particulars relating to the mortality from dengue fever during the first five months of this year, as recorded in this office. The details are as follows:—

Metropolitan Area (10 Miles).

Month	Population, Dec. 31, 1903	Total Deaths	Deaths from Dengue Fever					
			Under 5	5 to 20	20 to 40	40 to 60	Over 60	Total
January	125,672	M. 76	..	..	..	..	..	..
		F. 40	..	..	..	..	..	
February ..		M. 63	..	..	1	..	1	2
		F. 55	..	..	..	..	..	
March		M. 85	2	..	2	..	10	39
		F. 96	11	1	2	4	7	
April		M. 81	11	..	4	1	6	43
		F. 61	5	3	2	4	7	
May		M. 68	1	..	1	..	1	9
		F. 57	5	..	..	..	1	
Total		M. 373	14	..	8	1	18	..
		F. 309	21	4	4	8	15	
		682	35	4	12	9	33	93

I have the honour to be, Sir,
Your obedient servant,
(*Signed*) Thornhill Weedon,
Government Statistician.

Dr. A. J. Turner,
Wickham Terrace, Brisbane.

P.S.—One death from dengue, that of a male, aged 60, was reported in June; none in July.

Appendix II.

Dr. Lockhart Gibson reports three cases of keratitis during dengue, and five cases (three adults and two children) occurring immediately subsequent to the attack or during convalescence.

The latter he considers to be examples of "keratitis neuro-paralytica" from neuritis of the corneal terminations of the ciliary nerves. A triangular area, with its base at the corneal margin and its apex at or beyond the corneal centre, is involved, and becomes insensitive. Some of the cases are serious, and all are extremely slow in recovering, owing, doubtless, to persistence of the neuro-paralytic state of the cornea.

In the cases of keratitis observed during the actual attack, in each case an irregular and prolonged one, he considers that, in addition to keratitis neuro-paralytica, there was infective ulceration of the cornea, probably directly induced by the infective organism of dengue. Of four eyes involved, one cornea, an adult's, became entirely destroyed. In two other cases, twins aged 10 months died from prolonged attacks of dengue, with recurring hyperpyrexia. Prior to death one cornea of one became staphylomatous, and each cornea of the other had a large perforation, due to the formation and separation of a slough.

so that the delicate needle, supported in its groove, is protruded, and forced into the tissues of the victim. In all these forms, the gnats included, suction is effected by the pumping action of an expansion of the pharynx contained within the head, which can be actively dilated by means of powerful muscles.

In the true flies the food passes from the pharynx into a large, thin-walled crop, placed in the anterior part of the abdomen, from which it is regurgitated, little by little, through a valvular organ, known as the proventriculus, into the mid-gut for leisurely digestion. In the gnats, however, the crop has ceased to function as such, and is transformed into a pneumostatic organ by the enormous development of the tracheal supply of its walls, so that the increase of the insect's weight, when heavy with food or eggs, can be met by a proportionate increase of its bulk. All forms are furnished with modified salivary or poison glands, which discharge by a common median duct at the extremity of the pharynx directly into the tissues of the victim. The action of the secretion is, no doubt, to keep the blood fluid and stimulate its flow, but repeated personal experience has convinced me that, in the mosquitoes at least, its primary action is anæsthetic, and that the subsequent irritation does not, as a rule, commence until the insect has flown safely away.

"Journ. Amer. Medical Association," September 2, 1905.

I.—Cysts of the Spleen. W. A. Bryan, M.D.

Bryan classifies splenic cysts into: (1) Dermoid cysts characterised by being lined by epithelial cells. (2) Simple serous or blood cysts, believed usually to be due to extravasation of blood, which has taken place either immediately beneath the capsule or in the substance of the spleen. (3) Echinococcus cysts. Splenic cysts when small present no symptoms, but as they advance in size and attain adhesions, their presence is indicated by pain and fulness in the left hypochondrium. Of 17 cases, of which careful notes are available, 5 were ascribed to injury, 5 to malaria, and in 2 cases malaria and injury were recorded.

Treatment.—Splenectomy is called for when the splenic tissue, owing to the cyst, is considered organically useless. When adhesions forbid complete removal, and when the cyst has not destroyed the splenic tissue altogether, the sac must be opened and drained. Exploratory punctures of the spleen are to be condemned in cases of cysts of the organ.

II.—Indications for the Removal of the Pathologic Spleen. B. B. Davis, M.D.

Davis, in his summary of indications for removal of the spleen, states:—

(1) Splenectomy is contraindicated in leukæmia, amyloid spleen, hypertrophy secondary to hepatic cirrhosis, secondary malignant disease, and in essential anæmias.

(2) Splenectomy is indicated in cysts, benign tumours, tuberculosis, sarcoma, rupture when extensive, malarial spleen, and in splenic anæmia, when the organ is very large and other treatment fails.

In wandering sleen, splenectomy is usually preferable to splenopexy. In abscess of the spleen drainage is preferable to removal of the organ.

Business Notices.

1.—The address of the Journal of Tropical Medicine is Messrs. Bale, Sons & Danielsson, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the Journal of Tropical Medicine. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied free with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,	5/-;
100	„ „	6/-;
200	„ „	7/6;
50	Copies beyond four up to eight pages,	8/6;
100	„ „ „	11/-;
200	„ „ „	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

IS MALTA FEVER PECULIAR TO MALTA?

The name Malta fever has been regarded as one of those irregularities in regard to nomenclature with which we are familiar. Up to quite recent years almost every district or even town in warm countries had its own specially named form of illness which was regarded as specifically belonging to the place. Since the parasites have been discovered, and the diseases have been submitted to accurate tests, there are but few of the names we are familiar with that will stand the criticism. "Rock fever," "West Coast fever," "Delhi boil," "Biskra button," "Hong Kong dog," "Shanghai fever," for example, have no title to the geographical limits placed upon them by their baptismal names, and there are no doubt many others that will disappear in time. The name Malta fever has been similarly dealt with, but it is possible that in this disease, at least, we

have gone too far. Malta fever being considered a term too restricted in its meaning, the name Mediterranean was given the disease, and yet again Undulant fever advanced it to a more general platform. Reports from many countries far from Mediterranean shores indicated that the fever in question prevailed there, and cases of Malta fever have been reported from Gibraltar, almost all the islands of the Mediterranean, many parts of Italy, Greece, Turkey, Palestine, from several parts of Africa from Algiers to Zanzibar, from a dozen places in India, from Southern China, Philippines, and Fiji. In the Western Hemisphere also cases are reported from the Mississippi valley, Cuba, Puerto Rico, Venezuela, Brazil, and Monte Video. Staff-Surgeon E. A. Shaw, R.N., has shown that many of these reports are fallacious. The diagnosis has been in the majority of instances made upon clinical phenomena alone; the confirmation either by serum diagnosis or recovery of the *Micrococcus melitensis* during life or after death being altogether wanting.

One would have expected to find cases of Malta fever in the Italian and French Mediterranean littoral, but in not one instance have investigations by Staff-Surgeon Shaw confirmed the presence of Malta fever. The Neapolitan fever had been long suspected to be of the nature of Malta fever, but scientific tests have disproved the assumption. It would therefore seem that the belief that the fever with which the name Malta is associated had a wide geographical distribution is not true. It would even appear that the name Mediterranean is not deserved, for in none of the islands or towns on the seaboard of the adjacent continents has the disease been proved to exist endemically. The name may be an unfortunate one, but in this instance the local name would seem appropriate if not scientific, for there is every evidence to show that Malta fever is, to say the least of it, infrequent and rare elsewhere than in Malta.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the Journal of Tropical Medicine *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Journ. Amer. Medical Association," August 19, 1905.

(1) Status of Medical Affairs in the Philippine Islands. John R. McDill, M.D., Manila.

(2) The Elimination of the Mosquito. A. H. Doty.

(3) Ankylostomiasis or Uncinariasis. T. M. Russell Leonard, L.R.C.P., L.R.C.S.(Edin.), Grenada.

Leonard states that the chief difference between the *Ankylostoma duodenale* (the Old World variety) and *Ankylostoma* or *Uncinaria americana* (the New World variety), so named by Stiles, consists in the size and armature of the mouth. The *A. duodenale* is larger and possesses two pairs of hook-like ventral teeth and one pair of dorsal; the *A. americana* is smaller and possesses two pairs of ventral plates or lips, and one dorsal pair. In Grenada the large majority of cases show the Old World parasite. The disease occurs more frequently in country villages than in the large towns, owing chiefly, no doubt, to the fact that fæces are there deposited on the earth among the bananas and cocoa trees.

In every case of ankylostomiasis amongst natives notified by Leonard pigmentation of the tongue was observed.

He is inclined to attribute the black on the tongue to (1) blood changes in which the hæmoglobin is disintegrated; and (2) disturbance of the nervous system by the toxin produced by the parasite.

Treatment.—A saline aperient at 10 p.m. on the night prior to administration of the thymol is given. The following morning a pint of milk is given and two hours afterwards the thymol.

The drug is exhibited in cachets, 5 grains for a child and 40 grains for an adult, and one cachet is taken every hour till 15 grains are given to the child and 120 grains to the adult. No food is allowed for four hours after the last cachet, when a saline aperient is again taken. The aperient used is sodii sulph. and mag. sulph., āā ʒiss., aqua ad ʒii. for a dose. Beyond some slight dizziness and a sensation of fainting, the administration of thymol has caused no untoward symptoms in Leonard's practice.

The prophylaxis resolves itself into (1) prevention of water infection; (2) prevention of soil infection; (3) treatment of all cases of disease.

(4) A Case of Ainhum. F. Wheatland, M.D.

Wheatland reports a case of ainhum in a negro woman, aged 53, born in Queen Anne County, Maryland. Her father, partly Indian, had lost two toes when about 23 years of age; the cause unstated. The patient had lost the little toe of the left foot after about four years from the first appearance of the constriction at the root of the toe; the right little toe presented, at the time of the report, a deep sulcus round its root. A case of ainhum was reported by Dr. Brayton in the *Journ. Med. Assoc.* of July 8th, 1905.

"Journ. Amer. Medical Association," August 5, 1905.

PFEIFFER'S GLANDULAR FEVER—DRUESENFIEBER.

Glandular fever (Pfeiffer) is ushered in with rigors, headache, pain in the throat and increase of temperature. Soon after the initial symptoms the cervical glands, more especially those around the sterno-mastoid muscle, are enlarged. During the course of the disease acute hæmorrhagic nephritis occurs, and the spleen and liver enlarge. The glands remain discreetly enlarged, rather hard and not very tender. There is eruption on the skin or mucous membrane of the mouth. After three to five days the throat symptoms and feverishness disappear, but the swelling of the glands remains, usually for a week. A death from the disease has not been recorded.

The treatment recommended is: Unguentum Credé (collargol 15, adeps benzoata 75, cera alba 10) applied to neck glands, and the usual treatment for nephritis.

Notes and News.

MEDICAL COLLEGES IN THE UNITED STATES OF AMERICA.—According to the returns for 1904-5, there are 162 medical colleges in the United States, with 26,147 students.

ANISEED AS A GALACTAGOGUE.—Burzagli (*Gazz. degli Osped.*) recommends 25 per cent. infusion of aniseed as a galactagogue. A litre of the infusion is to be drunk during the twenty-four hours, and the breasts fomented with the infusion continuously for some days. It may be noted in this connection that systematic fomentation of the breasts is a good means of promoting the flow of milk even without the addition of aniseed; whilst also copious draughts of plain water or milk are useful adjuncts. It may be the aniseed plays but a small part in producing the flow, but suggestion helps in this physiological act as in others.

JAPANESE MEDICAL MEN AND BRITISH REGISTRATION.—A communication has been received by His Majesty's Government requesting on behalf of the Japanese Government "that steps may be taken so that Japan may be recognised as one of the countries to which the Medical Act of 1886 applies, thus enabling Japanese medical practitioners to practise medicine in the Straits Settlements as well as in other parts of the British Empire."

WELFARE WORK.—The endeavours of Messrs. Burroughs Wellcome and Co. to promote the moral, mental and physical betterment of their people have received recognition at the Liége International Exhibition, just closed. A special gold medal was conferred upon them for the "intellectual and moral development of workers."

SHEFFIELD UNIVERSITY is the latest addition to the growing list of English universities.

Reviews.

A PRACTICAL GUIDE TO COOKERY IN WEST AFRICA AND THE TROPICS. By Sister COCKBURN, late Colonial Nursing Service, Sierra Leone, West Africa. London: The Scientific Press, Ltd., 28 and 29, Southampton Street, Strand. Pp. 160, price 3s. net.

The Scientific Press has published several excellent books on hygienic lines, and the present volume will prove one of the most useful. Sister Cockburn has not only given recipes for invalid cooking, but describes how food may be prepared for healthy folk. There can be no doubt that lack of ability to obtain dainty food is a great drawback to life in the Tropics. The materials are limited to an extent impossible for people in Britain to comprehend; beef and mutton, if available at all, have neither the tenderness nor the nutritive value of home-grown meat, and unless carefully prepared become repugnant to the palate and impossible to digest. Fish in the Tropics has not the flavour of fish from British waters, and there are but few edible varieties.

These drawbacks Sister Cockburn tells us how to overcome, and her culinary suggestions are invaluable. Fowls although plentiful, are apt, from the frequency with which they appear on the table in all tropical countries, to pall upon the appetite, but the fowl sauté, pilan, pooloot, Ashanti fowl, and Spach-cock dishes described go a long way to relieve the monotony of this staple article of diet. Bananas are plentiful, of course, in West Africa, but the banana cream, fritters, and trifle which Sister Cockburn tells us how to prepare are welcome additions to the table. Such attractive names for dishes as Accra wafers, African snowballs, Bonny soup, Cape fillets, Cape goose, Gambia soup, Kohl rabi, Lagos pudding, Mango fool, Teneriffe pudding, Sherbro soup, and others, afford a plethora of change which must be appreciated highly by those who have to put up with native cooks and their cookery. The fruits and recipes given in the book are useful for any household, but for tropical residents they must prove especially serviceable; and if followed will not only reduce the monotony of the meals which is apt to prevail to an inordinate extent in warm countries, but will prove a potent factor in preserving health and preventing disease.

A MANUAL OF CLINICAL CHEMISTRY, MICROSCOPY AND BACTERIOLOGY. By M. KLOPSTVOCK and A. KOWARSKY, of Berlin. Translated by THEW WRIGHT, M.D. Rebman Ltd., 139, Shaftesbury Avenue, London, 1905. Pp. 296, price 8s. net.

This book, which has been popular in Germany for some time, should prove useful to all English-speaking medical men. It is concise, practical, and thoroughly up to date. For medical men in the Tropics we know of no work of the kind which so completely meets their special wants.

A PLEA FOR THE MORE ENERGETIC TREATMENT OF THE INSANE. By CHARLES WILLIAMS, L.R.C.P., L.R.C.S. H. J. Glaisher, 57, Wigmore Street, Cavendish Square, London, 1905. Pp. 51, 1s. 6d. net.

This book will serve to stimulate medical men to consider whether the lethargy which has so long obtained, in regard to the treatment of the insane, might not with advantage be laid aside.

NEW BOOKS ON GENERAL LITERATURE RELATING TO THE COLONIES AND INDIA.

The Empire and the Century. A series of Essays on Imperial Problems and Possibilities. By various writers. 8vo, pp. xxiii.-895. London: John Murray, 1905. (Price 21s.)

Stow, George W., F.G.S., F.R.G.S.—The Native Races of South Africa. A history of the intrusion of the Hottentots and Bantu into the hunting grounds of the Bushmen, the aborigines of the country. Edited by George McCall Theal, Litt.D., LL.D. 8vo. London: Swan, Sonnenschein and Co., Ltd., 1905. (Price 21s.)

Mingard, W. Yere.—Round the World: Our Colonial Cousins, or Britain Beyond the Seas. 12mo, pp. 288. London: T. C. and E. C. Jack, 1905. (Price 1s. 6d.)

Hooker, Sir Joseph Dalton (K.C.S.I., C.B., M.D., D.C.L., F.R.S.).—Himalayan Journals, or Notes of a Naturalist in Bengal, the Sikkim, and Nepal Himalayas, the Khasa Mountains, &c. 8vo, pp. xxxi.-574. London: Ward Lock and Co., 1905. (Price 6s)

Lyne, Robert Nunez (F.L.S., F.R.G.S.).—Zanzibar in Contemporary Times: a Short History of the Southern East in the Nineteenth Century. 8vo, pp. xii.-328. London: Hurst and Blackett, 1905. (Price 10s. 6d.)

Lawson, Sir Charles.—Memories of Madras. 8vo, pp. xiii.-313. London: Swan Sonnenschein and Co., 1905. (Price 10s. 6d.)

Hill, J. G.—The Calvert Scientific Exploring Expedition (Australia, 1896). Sm. 4to, pp. viii.-44. London: George Philip and Son, 1905. (Price 2s.)

The Bahama Islands.—Edited by George Burbank Shattuck, Ph.D. Royal 8vo, pp. 630. New York: The Macmillan Co., 1905.

Pullen-Burry, B.—Ethiopia in Exile, Jamaica Revisited. 12mo, pp. 288. London: T. Fisher Unwin, 1905. (Price 6s.)

Patel, J. M. Framjee.—Stray Thoughts on Indian Cricket. 8vo, pp. xvi.-175. Bombay: The *Times* Press, 1905. (Price 9s. 6d.)

Grant, William Lawson, and Hamilton, Frederick.—George Munro Grant. 8vo, pp. 531. Edinburgh: T. C. and E. C. Jack. Toronto: Morang and Co., 1905. (Price 12s. 6d.)

New Instruments, &c.

TWO NEW MICROSCOPE OBJECT GLASSES.—R. and J. Beck, Ltd., 68, Cornhill, London, E.C., have just brought to our notice two useful lenses.

[⅔ *inch* 16 *mm. focus*, 32°., *price* 15s.]

Our present Series A ⅔ inch object glass has an aperture of 17°, and whilst such a low aperture gives extra penetration or depth, we have brought out the new lens with the large aperture of 32° as being more suitable for flat sections. It has greater resolving power and flatness of field than the present Series A ⅔ inch, and is recommended except where great penetration is required.

[⅛ *inch* 4 *mm. focus*, 110°, *price* £1 10s.]

Our present Series A ⅛ inch has an angle of 90°, and the new lens gives greater resolving power, but less penetration. The resolving power of our present lens has been generally considered adequate for histological work, but there is a growing tendency towards wider-angle lenses.

COLONIAL CIVIL SERVICE.

MR. HENRY B. WALCOTT, Treasurer and Collector of Customs of British Honduras, is acting as Colonial Secretary of that Colony in place of the Hon. H. E. W. Grant, who has left Belize on promotion to the Colonial Secretaryship of the Falkland Islands. Mr. Walcott will continue to perform the duties of his substantive office in addition to those of Colonial Secretary.

Mr. L. W. Booth has been appointed District Judge, Commissioner of Requests, and Police Magistrate at Batticaloa, Ceylon. He has been in the Ceylon Civil Service for twenty-seven years, and has served in all parts of the Colony. Prior to proceeding on leave last year he was the Government Agent for the North Central Province.

Mr. Laurence Macrae is to succeed Mr. Neil F. Mackay as Private Secretary to the Premier of British Columbia and Assistant to the Statistician of that Province of the Dominion.

Lieutenant A. J. R. Dewar, of the Malay States Guides, has been selected for the office of an Assistant Superintendent of Police under the Government of the Straits Settlements.

Dr. A. R. Wellington has proceeded to Sarawak as an Assistant Medical Officer. He was formerly Assis-

tant Medical Officer of the Kensington Infirmary, which office he recently resigned.

Mr. Eric Maxwell becomes a member of the Council of the State of Perak, Federated Malay States, during the absence on leave of Mr. Francis D. Osborne for twelve months.

Mr. Stanley Fisher, President of the District Court, Kyrenia, Cyprus, is coming to England on leave of absence, during which his duties will be performed by Mr. J. C. Macaskie, President of the Famagusta District Court.

Mr. W. E. U. Grove has resumed the duties of Superintendent of Police, Malacca, Straits Settlements, and is also acting as Harbour Master and Conservator of the Port of Malacca in addition to his other duties.

Mr. R. M. Little, Resident of Kudat, British North Borneo, will leave England early in January to resume duty after leave of absence.

Mr. W. L. Kindersley, late Assistant Government Agent, Trincomalee, Ceylon, has taken over the duties of Assistant at Chilaw to the Government Agent of the North-West Province.

Mr. F. G. Stevens, who was formerly connected with the Straits Civil Service, which he entered as a cadet in the year 1902, has been made a magistrate of the first class for the District of Raub, Federated Malay States.

Mr. H. A. Adams is acting as Superintendent of the Public Works Department, Sarawak.

Sir Alfred Sharpe, K.C.M.G., C.B., Commissioner of the British Central Africa Protectorate, leaves Marseilles on the 23rd instant on his return to duty.

The Governorship of British Honduras will probably become vacant at an early date, as Sir Bickham Sweet-Escott, K.C.M.G., who has been granted an extension of leave until the end of February, is not expected to return to the Colony.

Mr. P. J. Sproule is acting as Deputy Public Prosecutor, Singapore, in consequence of the transfer of Mr. W. L. Woodward to one of the newly created judgeships in the Federated Malay States.

His Excellency E. P. Gueritz, who recently resigned the appointment of Governor of British North Borneo, has withdrawn his resignation, and is administering the Government.

A proposal is to be submitted to the Ceylon Legislative Council, with the approval and consent of the Secretary of State, for the increase of the salaries of all classes of the Civil Service of Ceylon, at a total cost to the Colony of Rs. 500,000 per annum. The subject has engaged the attention of the Secretary of State and the Governor of the Colony for the past two years, and it is expected that the scheme will partly come into force on January 1st.

Dr. J. W. Farndale has been appointed District Surgeon of Mwomboshi, North-east Rhodesia, by the British South Africa Company. He sails before Christmas.

HOMBURG Salt, prepared from the water of the well-known Homburg Elizabeth Spring, is sent by Rüdiger and Co. (Homburg v. d. Hohe), in bottles for trial purposes. These are always at the disposal of the medical profession, and will be sent free of all charges.

NEW ZEALAND DRIED MILK.—This product is most highly spoken of by all public health authorities. It is now classified as "A Standardised Product," and it is pronounced to be immensely superior to any of the condensed milks. Although no preservatives are added to the milk, it keeps for months, even after the tin is frequently opened. When known how carefully cows are inspected in New Zealand, and how rigidly severe are the laws in that country concerning the adulteration and "faking" of milk, and how enthusiastically the public health authorities speak of its qualities as a substitute for human milk, the "New Zealand Dry Milk" (Defiance Brand), prepared by the Imperial Dry Milk Company, Ltd., of Wellington, New Zealand, may be safely accepted as a genuinely hygienic article of diet. For travellers and for residents in the Tropics where fresh cows' milk is, as frequently happens, not to be had, the excellence of the "New Zealand Dry Milk" will play an important part in the maintenance of infant life in warm climates.

The proprietors have, indeed, already received satisfactory testimonials from medical men in the Tropics as to its efficacy in infantile diarrhœa and dysentery. In military campaigns also, and in the navy, this product will prove a boon, being pure, palatable and very portable. The "Defiance" brand of dried milk was put to a practical test recently in this connection, being the only milk supplied to the sailors and soldiers engaged in the Royal Naval and Military Tournament at the Agricultural Hall this year, and the P.M.O. in charge reported on it as "a valuable substitute for ordinary milk, handy, and hard to distinguish from boiled milk."

In hospitals, asylums and other public institutions its usefulness is undeniable.

Subscriptions.

POST FREE.

No. 1.

BASUTOLAND.

Medical Report for the Year ending December 31st, 1903.

By EDWARD CHARLES LONG, M.R.C.S., L.R.C.P.

Principal Medical Officer.

Population.

No estimate of population which would be of any value is possible at present. The coming census should however provide some interesting information for next year's report. In 1899 the population was estimated at 270,000, including 700 Europeans.

General Health of the District.

The year under review may be said to have been an average healthy one. There have been but few epidemics, and none of importance, with the exception of *Scurvy* and *Pneumonia*, to which reference will be made later.

Whooping Cough

Was prevalent during the winter, and rather more cases of bronchial affections were noticed, but they were mostly of a mild nature.

Enteric Fever.

There were fewer cases of *Enteric Fever* than usual. Some districts were practically free of this complaint throughout the year.

Intestinal Disorders.

There was the usual amount of *Infantile Diarrhœa* in the summer months, mostly traceable to improper feeding.

Most of the cases of *Dysentery* which were admitted to the hospital occurred in labourers returning from work in neighbouring territories.

Leprosy.

The increase in the number of lepers recorded is due to the investigation which was undertaken during the year, and concerning which a full report has been made to the Colonial Office.

Syphilis.

Except in the *Tertiary forms*, *Syphilis* shows a slight decrease for the first time, a most satisfactory feature, as the disease is one of the greatest scourges in the country. The natives seem to appreciate more aud more the value of treatment in this disease, and the knowledge that it can be cured has spread to the remoter districts. People frequently come or send many days' journey to ask for medicine. I have in previous reports referred to the appalling tertiary cases which are so common. The people have lately coined a word "moto" to designate one of the commonest lesions, viz., phagedænic ulceration of the fauces and palate, which they look upon as a distinct disease, and they have likened its ravages to that of moth in blankets, "moto" being a corruption of the Dutch word "mot."

New Growths.

There has been an increased number of *Benign Growths* treated, and since the date of the circular issued by the Cancer Research Committee a considerable number of specimens has been despatched to the Director of the Committee.

The few cases of *Malignant Disease* noted were not of much value scientifically, owing to the rooted aversion to *post-mortem* examinations exhibited by friends of deceased patients. Consequently scarcely any specimens of this kind are ever available.

Diseases of the Eye.

Ophthalmia of a mild type was as usual noted throughout the year, and was not affected by the seasons.

The considerable increase in the number of *Cataract* cases treated is due to the fact that the people are gradually learning that the disease is capable of relief. Forty cases were successfully operated on; they were all of the senile variety.

The prevalence of *Glaucoma* is noteworthy. Unfortunately the bulk of the cases only come when the glaucoma is absolute and beyond relief.

A good many *Cases of Blindness*, due to the destruction of the cornea from small-pox, have been seen. These patients have often heard of friends who have been successfully operated on for cataract, and it is most distressing to have to send them away unrelieved.

In some cases in which the cornea is not hopelessly destroyed Darier's method of subconjunctival injections is now being tried at Maseru Hospital, and Dr. Jones hopes in my next report to be able to embody the results of the trial.

Generative Organs.

An increasing number of *Diseases of the Female Generative Organs* is noted. Subinvolution from improper care after parturition is the most common.

One case of malformation deserves notice on account

of its rarity, viz., *Congenital Absence of the Vagina.* patient was a girl of about sixteen years of age, and attention was first called to her condition by the absence of menstruation. The external genitals were small, but otherwise normal. The vagina was entirely absent, and represented by a fibrous cord. The uterus and ovaries were present, but infantile in type. An exploratory operation was performed, but the case was found to be beyond the scope of surgical interference. In connection with this case I may state that about two years ago I operated successfully on a case of partially occluded vagina in a young native woman.

Digestive System.

Functional Disorders of the Digestive System were, as usual, very numerous, and are mainly due to injudicious diet.

Meteorology.

The meteorological conditions in 1903 were very unfavourable to the public health. There was a failure of the late summer and autumn rains, with very early frosts, which destroyed most of the scanty crops which had survived the dry weather. The winter was cold and dry, and extraordinarily windy and dusty. There was a prolonged drought in the spring which destroyed the wheat crop, and deprived the people of the food they are accustomed to depend on till the mealies ripen, besides preventing the growth of the wild spinach and other herbaceous plants which are used as an article of diet in the spring and early summer months. The drought persisted through the first two summer months, although some rain fell in November and December. Windy weather with dust may be said to have prevailed during six months of the year.

The total rainfall for the year was 12 inches below the average. The effect of such inclement weather on the health of the people was twofold. Firstly, it entailed a general scarcity of the staple food of the country, with a consequent general lowering of vitality. The scarcity had to be made up by the importation of grain, which in the main was of very inferior quality, and in some cases positively harmful. The absence of the usual supply of fresh grain (wheat) and green vegetable food in the late spring and early summer months accentuated this. Hence the prevalence of scurvy and digestive troubles. Secondly, the cold, windy, and dusty weather of the winter and spring months was indirectly responsible for the prevalence of pneumonia and bronchial troubles.

Epidemic of Pneumonia.

The number of cases of pneumonia recorded does not afford a correct estimate of the extent of the epidemic. From information supplied to Dr. Long, he judges there was a considerable number of deaths from this complaint in July and August, the months when the disease was most prevalent in other parts of South Africa. Certainly the type of disease in the cases which came under his immediate notice was much more severe than have been accustomed to be observed here in former years, and the death rate was proportionately high.

Prevalence of Scurvy.

Mild cases of this disease have from time to time been observed in Basutoland, but during 1903 a considerable percentage of the people have suffered, and there have been many deaths. A large number of the cases occurred in labourers returning from work in neighbouring territories. Many of these arrived in Basutoland in a pitiable condition. So common has scurvy been during 1903 that the Basuto have coined a word to describe it. They call it "mochecha fatsi," which means to propel oneself on the haunches by the aid of the hands, this being the only way in which advanced cases with painful brawny swellings of the calves are able to move about.

During the month of December, when the epidemic was at its worst, Dr. Long examined a large number of out-patients for signs of scurvy, and discovered indications of the disease in a considerable percentage of those who sought relief for other diseases. An examination of a batch of labourers destined for the Koffyfontein mine led to the rejection of 25 per cent. on account of incipient scurvy.

So far as observed here, the symptoms of scurvy do not differ from the classical symptoms described in text-books. Swollen, spongy gums, which bleed readily, offensive breath with dry, harsh skin and great weakness and prostration, are early symptoms. Great pain in the lower extremities is complained of, and in advanced cases there were always brawny, painful swellings of the calf muscles. Subcutaneous hæmorrhages were rarely observed. Adults, especially males, seemed most liable to the disease. Few cases were observed in children. The mortality was highest in young male adults, especially those who had been working on the railways and mines.

The cause of the epidemic has already been referred to. Certainly in Basutoland Dr. Long considers the bad quatity of the imported grain to be largely responsible.

The treatment of cases was beset with difficulties, owing to the impossibility of obtaining anti-scorbutic articles of diet. Lime-juice we found nearly useless when the disease was well established. It was valuable, however, as a prophylactic in the gaols, which were, with the exception of two cases, quite free of the disease.

The most rapid cure was obtained by the addition of oranges to the diet. Unfortunately the available supply only permitted of this remedy being used in a few cases. As regards drugs, citric acid, with large doses of cinchona, seem to afford most relief.

Sanitary Conditions.

The sanitary condition of the territory calls for no comment. The water supply at most stations is still insufficient. At Mafeteng and Leribe the deficiency was most acutely felt, and was much intensified by the phenomenally dry year. Schemes for obviating this in future have, I understand, been already drawn up and authorised.

Vaccinations.

Sixty thousand five hundred and fifty-five Vaccinations were performed during the year, all with calf lymph supplied by the Cape Bacteriological Institute.

The following return of cases treated at the Hospitals is attached to this report:—

No. 2.

ST. KITTS-NEVIS AND ANGUILLA.

Medical Report on the Sanitary Condition of the Presidency of St. Kitts-Nevis and the Island of Anguilla, with Statistical Tables for the Year ending December 31st., 1903,

By W. H. FRETZ, L.R.C.P., L.R.C.S.Edin.

Population.

The population during the year 1903 was for St. Kitts, 30,314; Nevis, 13,422; Anguilla, 4,073; and that the death-rate was for St. Kitts, 30·77 per mille, against 26·17 per mille in the previous year; Nevis, 23·61 per mille against 21·87 per mille in the previous year; Anguilla, 23·07 per mille, against 18·88 per mille in the previous year; while the birth-rate was for St. Kitts, 36·55 per mille, against 35·70 in the previous year; Nevis, 40·38 per mille, against 44·93 in the previous year; Anguilla, 40·90 per mille, against 28·43 in the previous year.

Birth-rate.

The birth-rate is interesting, as will be seen from the following tabular statement:—

—	Legitimate Births	Legitimate Birth-rate per 1,000	Illegitimate Births	Illegitimate Birth-rate per 1,000
St. Kitts ..	378	12·40	711	23·40
Nevis ..	228	17	312	23·30
Anguilla ..	105	26·20	91	22·70

The Public Health

Of the inhabitants was good. There was an absence of any widespread outbreak of any serious epidemic disease.

Malaria.

Malarial Fever has hitherto not been endemic in this Presidency, but owing to the frequent emigration and immigration now going on to and from islands where cases always occur, the tendency to endemicity is beginning to prevail, and at certain seasons of the year may even prove to be epidemic. The most common type of fever in this island is the remittent, and is found among all classes.

Chicken-pox.

This mild infectious disease has been reported from several parts of the Presidency, though it never became epidemic.

Intestinal Disorders.

Dysentery seems to have been fairly distributed throughout the Presidency.

Diarrhœa prevailed generally, and though not in an epidemic form, contributed largely to the death-rate, chiefly of infants.

Leprosy.

The total number of cases in the Lazaretto on December 21st, 1903, was sixty-two, against seventy-one in the previous year; two new cases were received, against eight in the previous year. The question as to the necessity of the segregation of lepers has recently been contested, but if it be conceded that leprosy is caused by a germ, then the leper must be regarded as a source of danger, and the most effectual way of suppressing the disease seems to be by the thorough isolation of existing lepers; wherever the disease has been treated by such it has slowly but surely died, but where it has not, the disease has continued and still prevails. It is impossible to state if this disease is on the increase in this island; the compulsory notification of leprosy may prove useful in this connection. The benefits gained by the Presidency by having in its midst such an institution as the Lazaretto have been abundantly proved, providing, as it does, for those who have no homes and no means of protecting themselves.

Yaws.

From the reports of the District Medical Officers, this disease seems to be on the increase in the Presidency. As sanitary methods become more generally known through recent legislative measures, we trust it may show a marked decrease. A valuable paper on this subject by Dr. Rat, of Anguilla, is appended.

Tuberculosis.

A diseased condition of a specific and infective nature, which occurs in different forms, is very prevalent among our coloured population, who seem very susceptible to its ravages; 158 deaths are attributed to tubercle during the year under review.

Cancer.

Eighteen deaths are placed under this heading. Our native population are not very prone to this dreadful malady.

Sanitary Condition.

The general sanitary condition of the Presidency remains in much the same condition as last year; the same method of disposal of fæcal matter exists, but the subject has been considered by the Town Board of Basseterre, and a more sanitary method to take the place of the present one is under consideration. The town of Basseterre seems to be extending, and urgent methods should be taken to keep it in as sanitary a condition as possible.

Port sanitation is a chief consideration, and a first line of defence to the town against disease is the sanitation of the port.

The dust is objectionable and detrimental to health, and the streets should, if possible, be watered more frequently to allay this nuisance. The scavenging is good. The water supply is of good quality, but during a long drought is a source of some anxiety.

The houses of the poor need much improvement, and attempts should, if possible, be made to make these more healthy and sanitary.

The Medical Officer of District 5 (Dr. Foreman) reports as follows: "In my district the first three-quarters of the year were pretty healthy, but the last one was very unhealthy, diseases of the digestive and respiratory organs being prevalent. I am sorry to say that yaws is on the increase in this part of the island."

The Medical Officer of District 6 (Dr. Bell) reports as follows: "The health of District 6 was not satisfactory during last year. Malarial fevers, chiefly of the remittent form, prevailed in the early and late months, and diarrhœa and dysentery in children and adults during the warm season."

The Medical Officer of District 7 (Dr. Cooke) reports as follows:—

"(1) The past year has not been remarkable in this district for the occurrence of serious epidemic disease, nor was it possible to note any particular seasonal prevalence, with perhaps the exception of the usual increase of intestinal disorders in children during the hot months.

"(2) There were a few cases of varicella about the middle of the year, but the disease did not become epidemic; and the sporadic cases, which included adults as well as children, did not present much constitutional disturbance, nor require much in the way of treatment.

"(3) The education of the people in sanitary matters makes very slow progress, and the results of dirt and poverty are very manifest, even to a casual observer. In this connection, I may mention, there has been a great prevalence of tinea taral amongst the children of the district. Yaws also is widely spread throughout the island, and seems to be on the increase.

"In attempting to combat these diseases the greatest difficulty is experienced in getting the people to continue treatment, in conjunction with cleanliness, long enough to be effectual.

"(4) As the number of emergencies this year has been few, the majority of the cases treated at the Nevis Emergency Ward have been badly ulcerated legs in young adults, a class of case of very frequent occurrence in the district, and mainly the result of neglected yaws, or poverty and yaws combined, so that the beds have been occupied one way or another throughout the year."

Health of Anguilla.

The Medical Officer of Anguilla (Dr. Rat) reports as follows: "There is nothing special to report with regard to the health of Anguilla during the first two quarters of the past year.

"The third and fourth quarters were marked by a very high mortality, which was indirectly caused by the want of food from which the poorer classes suffered as the result of a long-continued drought.

"Malarial fever prevailed very extensively during the last quarter and still continues, chiefly in the eastern portion of the island, where the excavations caused in the limestone rocks by the rain form reservoirs where the mosquitos breed freely and undisturbedly. The fever did not present any of the several symptoms which characterised the previous epidemic. It showed rather a tendency to pass into the form of the pure intermittent after a few days of continued pyrexia, and to become chronic."

Vaccinations.

During the year there were 1,657 cases of successful vaccinations, against 1,776 cases for the previous year. The children of this Presidency are well protected against small-pox, but the same cannot be said of its adult population. The Government in their wisdom have offered them re-vaccination, but they are not willing to avail themselves of the boon. Considering that small-pox in its natural state is one of the most loathsome, disfiguring, and fatal diseases, the only protection of any avail being vaccination, it will be a wise provision that re-vaccination be made compulsory by law, and that it be performed during the ages of 10 and 13 years.

Health Ordinances.

Two legislative enactments which came into force during the year are of medical interest, and must prove beneficial to the Presidency—No. 12 of 1902, and No. 13 of 1902. The former, the *Health Ordinance,* establishing local boards of health in the several country districts, and giving representative local residents control of their sanitary measures, must serve a useful purpose; the latter, the *Infectious Diseases Ordinance,* provides for the notification of infectious and notifiable dieeases, and the proper control of such. The coming into being of the Basseterre Town Board marks a new era in the management of the sanitary measures of the chief town, and much may be expected from it in progressive sanitation. The question of quarantine has been brought forcibly to notice of late; the want of uniformity in its rules and regulations has been apparent; the necessity for careful consideration of the whole subject under the light of modern views and theories has been abundantly proved. As the question is shortly to be discussed at a conference, it will prove no useful purpose to enter into the subject at this stage.

Medical Staff.

The Medical Staff of the Presidency is now complete with seven District Medical Officers, and Medical Superintendent of the Cunningham Hospital. In this connection I cannot conclude this report without reference to the retirement of Dr. W. J. Branch from the public service of the Presidency. Entering as a District Medical Officer in the year 1863, he devoted forty years of his life to assiduous and earnest medical work, gaining for himself universal respect. To the Cunningham Hospital he has devoted the best energies of his life; this institution owes more to him than any other man. To his junior colleagues and consultants he gave utter loyalty, with a strong professional instinct. He is still amongst us, ever ready to give of his fund of varied experience and knowledge, though retired from active duties.

"YAWS," BY DR. J. NUMA RAT.

Its introduction into Anguilla in 1903 (Anguilla is an island which lies sixty miles north-east of St. Kitts, British West Indies).

Yaws had not appeared in Anguilla within the memory of any of its inhabitants until June 1902, when a Negro, aged 8, an Anguillian, returned here from a visit to St. Kitts, with a fungating ulcer on one of her ankles, which proved to be the primary lesion of an attack of frambœsia.

There were at the time seven members (including the parents) of the family to which the girl belonged, the other children being two girls aged 14 and 5, a boy of 12 and an infant a few months old. They lived in a one-roomed thatched, unfloored hut, standing fifty yards away from the nearest dwelling.

In December, 1902, the eldest girl was suffering from a "scratch" on the upper part of her leg, which had suppurated, and she applied to it some of the ointment with which her infected sister was dressing the sore on her ankle. After a few days a fungating ulcer appeared on the site of the "scratch."

In January, 1903, the boy, aged 12, became infected with the disease through a wound on the foot, which shortly after began to fungate.

In June, 1903, the girl, aged 5, was infected through a fissure between two of her toes, which gradually spread into a fungating ulcer.

As there were no cases of yaws in the island when the girl returned here from St. Kitts, the nature of her disease was unsuspected, and the parents continued to treat the sore for several weeks as an ordinary ulcer. Nor do they seem to have attached any importance to the squamæ and papules which appeared on the patient between June and December, 1903.

Nor even when the eldest daughter was infected was the disease recognised.

It was not until January, 1903, when the schoolmaster brought for my inspection the boy of 12, with a frambœsial granuloma on the scrotum, that it was discovered that yaws had been introduced into the island.

The disease followed the usual course in the four cases. There was first the characteristic change in the lesion at the site of infection, and then, after a few weeks, a general eruption consisting of squamæ and papules, of which only a very few developed into granulomata.

The treatment of all the cases consisted of perchloride of mercy in small, and perchloride of iron in moderate doses during six months. By June, 1903, the two elder girls showed no symptoms of the disease. The affection proved more rebellious to treatment in the boy, in whose case, after the disappearance of the general eruption in July, 1903, hard papules developed on the knees and fronts of the legs, and on the elbows and backs of the arms. These disappeared, as usual, very gradually, and even up to the present a few of them are yet to be seen.

The boy was also the only one in whom granulomata appeared on the soles of the feet. These persisted six months after the general eruption had disappeared.

The disease in the case of the youngest girl, aged 5, was of a much milder form, the cutaneous symptoms consisting only of squamæ and papules and a solitary granuloma on the back of the hip. On account presumably of the mildness of her attack, the mercury was not persevered with as in the other cases, and she still exhibits squamæ and papules, but no granulomata.

In addition to the mercury and iron internally, sulphate of copper was applied to the gramulomata on the soles of the boy's feet, and all the patients were washed with water and a soap containing perchloride of mercury. The application of this soap was considered by the mother of the children as very effective in getting rid of obstinate squamæ and papules, and it certainly seemed to be useful, both for that purpose and for preventing the appearance of any further eruption.

I have already pointed out in a previous paper the necessity of determining whether yaws is a purely constitutional disease, or whether, like tuberculosis, it may be either constitutional or local, or both. Different views have been held as to its nosology, and the present one is that it is a constitutional disease. It is, however, possible that its germs may affect the skin without invading the system generally, or, which appears to me probable, that while it may be a general affection resulting from the introduction of the virus through some cutaneous lesion, the microbes may subsequently find their way into the frambœsial eruption, thus aggravating it and producing the granulomata and ulcers which appear at later stages of the disease.

It is possible that the squamæ and papules are the only true secondary symptoms of the systemic infection, and that the granulomata are caused by an effort of the skin to repel the germs attacking it from without.

We have yet to learn also to what extent the system may become infected through the granulomata, and whether it is not through them that the virus is admitted which produces the eruptions supposed by some to be symptoms of a fresh infection, and by others to be further manifestations of the original attack.

Such considerations suggest the need of external applications which will not only destroy the granulomata and cause the disappearance of the squamæ and papules, but will also prevent the invasion of the skin by frambœsial or other microbes.

Germicidal remedies should be freely used with this object, and it is with this intent that I directed the bodies of the patients herein mentioned to be washed twice a day with the sublimate soap.

The floors of yaws hospitals should also be frequently disinfected, as well as the bed-clothes and apparel of their inmates.

Children discharged from a yaws hospital and allowed to return to the dwellings in which they contracted the disease are thus exposed to further infection. In such circumstances the eradication of the affection is an impossibility. If the houses in which they live have wooden or stone floors, these should be disinfected. If not, the upper layer of the earth within the houses and in their immediate neighbourhood should be removed to a sufficient depth and thrown away, after having been disinfected, and should be replaced by fresh uninfected earth. Such a measure would furthermore assist in preventing the infection of other members of the family.

SELECTIONS FROM COLONIAL MEDICAL REPORTS.

No. 3.

CEYLON.

Medical Report on the Health and Sanitary Condition of the Island for the Year ending December 31st, 1903, with the Hospital Returns for the same Period.

By Sir ALLAN PERRY, M.D., D.P.H.

I.—Population: Birth and Death-rates.

The estimated population of the Island on December 31st, 1903, was 3,740,562 (exclusive of the military and shipping population); 148,027 births and 96,084 deaths were registered. The birth-rate was 40·0 per mille against 38·5, and the death-rate 25·9 per mille against 27·5, in the previous year, calculated on the estimated population at the middle of the year.

II.—Public Health.

The public health during the past year has been good. There have been very few outbreaks of epidemic disease, and the numbers attacked for each of the more serious infectious diseases have been less than in 1902 (with the exception of enteric fever), *vide* Table I. :—

Table I.

	Cholera		Small-pox		Malaria		Enteric Fever	
	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths
1902 ..	179	116	146	35	6,513	115	243	63
1903 ..	46	23	29	5	4,766	108	358	71

Enteric Fever.—The increase in the number of enteric fever cases is, I doubt, not a real one; at the same time it must be remembered that the notification of these cases is becoming more general, and the bacteriological aid in diagnosis is more used by medical practitioners. In December an amended regulation for the notification of this disease was promulgated, which should still further increase the numbers notified. The number of cases of this disease treated in the several hospitals was 358, with 71 deaths, a death-rate of 19·83 per cent. The General Hospital, Colombo, returned the largest number of cases, viz., 212, with 36 deaths, a death-rate percentage of 16·98. Some of these cases were admitted to the hospital from ships. In the jails there were 26 cases of enteric fever, with 4 deaths, a death-rate of 15·38 per cent. The cause of the increase may be put down to contaminated water, for as long as cesspits and wells in close proximity to them exist, cases will increase in numbers.

Cholera.—It is satisfactory to note the small number of cases of cholera. This comparative freedom may be attributed to the closure of the North road coolie route, and to the quarantining of coolies at Ragama. The total number of cases was 46, with 23 deaths. The cases occurred in the Western, Central, and North-Central Provinces. The infection in nearly every instance could be traced to India.

The subjoined table shows the Provinces in which outbreaks occurred, the number attacked, the number of those who died, with their nationality :—

Table II.

Province	Number of Cases and Deaths		Nationality											
			Sinhalese		Moors		Tamils		Malays		Immigrants		Others		Total	
	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths
Western ..	1	1	—	—	—	—	—	—	—	—	1	1	—	—	1	1
Central ..	7	5	—	—	—	—	—	—	—	—	7	5	—	—	7	5
N.-Central	38	17	—	—	38	17	—	—	—	—	—	—	—	—	38	17
Total ..	46	23	—	—	38	17	—	—	—	—	8	6	—	—	46	23

Malaria.[1]—There has also been a marked falling off in the admission in the hospitals for malaria, but the deaths from the disease are half per cent. higher for 1903 than for the year previous.

Small-pox.—There were 29 cases of small-pox, with 5 deaths; they occurred in the Western, Central and North-western Provinces. Three cases came from Indian ports, 3 from Singapore, 7 from Colombo city, the others from out-stations and estates. Of the 29 cases, 7 were unvaccinated, 21 vaccinated, and 1 re-vaccinated. Of the deaths, 4 were unvaccinated and 1 vaccinated.

Chicken-pox.—There were 1,862 cases, with 4 deaths, reported. Most of these cases were treated in their own homes.

[1] Please see remarks on this disease under the heading, "Meteorological Condition and its Relationship to Disease."

Measles.—This disease did not assume any alarming proportions in any of the towns or villages.

Dysentery.—There were 2,384 admissions for this disease in the hospitals. The Western, Central and Sabaragamuwa Provinces were responsible for the largest numbers. The Eastern and North-Central Provinces had the fewest cases. The deaths in hospitals from this disease were 658, a percentage death-rate of 27·6. In the jails, 636 cases were admitted, with 20 deaths, a percentage death-rate of 3·14. The jails in the Colombo district contributed 445 out of the total jail admissions for this disease. December and January are the worst months for dysentery, and the reason of this, in my opinion, is due to the comparatively cold nights producing chills. Cholera belts and flannel shirts have been recommended for prisoners during this season. The above figures are instructive, as showing the much smaller death-rate in those who, like prisoners, are treated early. There is an order in the jails that any prisoner using a latrine more than twice in twenty-four hours must be seen by a medical officer.

Leprosy.—The total number of cases reported during the year was 589, against 560 in 1902, being an increase of 29 cases. The following is a return of lepers treated at hospitals and dispensaries, excepting those who were treated at Hendala and Kulmunai :—

TABLE III.

	1902.	1903.
Western Province	32	10
Central Province	28	27
Northern Province	9	1
Southern Province	29	17
Eastern Province	6	26
North-western Province	—	1
North-Central Province	—	1
Province of Uva	4	—
Province of Sabaragamuwa ..	40	28
Total ..	148	111

Four hundred and forty-seven cases were treated in the Leper Asylum, Hendala, and 31 in the Kalmunai wards. The new cases were admitted from the following places to the asylum at Hendala :—

Western Province	38
North-Central Province	1
Southern Province	16
Province of Uva	3
Province of Sabaragamuwa	10
Total	68

The Western Province, which includes the Colombo district, shows the largest number of cases. The Leper Ordinance has been in force two years. One hundred and twenty cases were reported during 1903 and 113 in 1902. Many have been accommodated in the asylum, and some have been isolated in their own homes, where conditions existed which allowed this.

There are 207 known lepers throughout the Island, whose names and addresses are registered, and who are periodically examined. They are in the non-contagious stage of the disease, and there is no room at present for them in the leper institutions. The approximate leper population may be put down at about 616.

A considerable increase in the accommodation for lepers will have to be made at Hendala, if they are all to be segregated. The extension of the female section is urgently required; this can be done by appropriating male ward 1 for females. Three new male wards to contain 50 beds each are also badly required, but more accommodation still will be required if all cases have to be isolated. The acquisition of more land for building purposes has quite recently been made. There are no punishment cells at Hendala; a few are required.

Kalmunai Leper Wards.—At this institution 31 lepers were treated during the year, of whom 18 were discharged relieved, 4 died, and 9 remained under treatment at the end of the year.

Ankylostomiasis.—This disease is constantly introduced from India by Malabar coolies, and is spread owing to their careless habits. This disease is on the increase. There were 1,775 admissions in all hospitals, with 272 deaths. The largest number was treated in the General Hospital, Colombo, viz., 756 admissions, with 38 deaths. A large number of cases occur in the planting districts. The danger of the disease exists in the profound anæmia, which so lowers the vitality that the victim is carried off by practically any intercurrent complaint. Improved sanitation is the principal means by which this disease may be combated. Proper latrines and the proper disposal of human excreta, if introduced into the planting districts, would check the waste of labour from this disease. Although only 1,775 cases were admitted into the hospitals, there are hundreds of coolies with this disease on them doing their daily work, and daily spreading the disease to others by fouling the soil and water-courses. It is a matter of impossibility to provide accommodation for all these cases in the hospitals, but much could be done on estates in the way of treatment.

Parangi.—This is essentially a disease of poverty. Whether it is a variety of syphilis or not, the fact remains that the better-nourished people of this Island do not suffer from it. As food becomes more easily obtainable by the extension of irrigation, and as sanitary methods become more generally known, this disease will show a marked decrease. The death-rate is remarkably small; out of 3,254 admissions for this disease during the year there were only 11 deaths.

Malignant Diseases.—There were 237 cases reported for the year, made up of 222 cases of "cancer" and 15 of "sarcoma."

Plague.—The same precautions against plague were continued during the year as have been in use for several years past. The Plague Committee has had fortnightly meetings. Plague hospitals at remote stations are not now kept up, but sites are ready and building materials at hand in case of necessity. On March 5th, 1903, a case of plague was landed from s.s. "Maria Valerie" at the Southern Plague Hospital, Galle; the patient was discharged cured on April 29th, 1903. The contacts were segregated and placed in quarantine for the full period of ten days.

Galle continues to be the plague port. The buildings at the plague hospital and the segregation camp are

fully equipped and ready for use at a moment's notice. A new disinfecting depôt has been established on the foreshore, where coolies who work on ships in quarantine can be disinfected, and where there is a steam disinfecting machine for the disinfection of soiled clothes. Accommodation is also provided for the disinfection of male and female saloon passengers.

The destruction of rats at the ports of Colombo and Galle was carried out during the year, with fumigation of cargo boats.

Table V. gives figures for 1902 and 1903 for comparison :—

TABLE V.—*Table showing the Primary and Revaccination in the Island during* 1902 and 1903.

	1902.	1903.
Primary vaccination :—		
Number vaccinated	142,141	146,428
Successful	121,273	126,538
Unsuccessful	9,382	11,008
Unknown	11,486	8,882
Revaccination :—		
Number vaccinated	7,760	4,510
Successful	4,652	3,013
Unsuccessful	1,500	799
Unknown	1,608	698
Primary vaccination :— Percentage of successful to total inspected	92·81	91·99
Revaccination :— Percentage of successful to total inspected	75·61	79·03

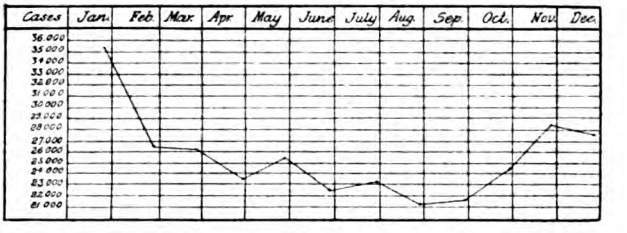
Vaccination.—During the year 150,938 subjects were vaccinated : 146,428 were primary vaccinations, and 4,510 revaccinations. Of the former, 126,538 were successful and 11,008 unsuccessful, and in 8,882 subjects the result of the operation was not known, as they failed to present themselves for examination on the appointed days. The percentage of successful cases to total inspected was 91·99. Of the revaccinations, 3,013 were successful and 799 unsuccessful, and the result was not known in 698 cases, as the subjects failed to present themselves for inspection. The percentage of successful cases to total inspected was 79·03. The Central Calf Vaccine Depôt at Colombo was opened on August 11th, and glycerinated calf lymph was supplied in sufficient quantities to all parts of the Island. The other depôts were closed during the year. The inhabitants of the Island are well protected against small-pox, and to this cause is due the prevention of the spread of this disease from the various foci that existed during the year.

III.—METEOROLOGICAL CONDITION AND ITS RELATIONSHIP TO DISEASE.

For the purposes of this report it has been thought advisable to roughly divide the Island into eastern and western portions. The eastern contains the districts affected by the north-east monsoon and the western by the south-west monsoon. The figures show the total number of cases of disease, number of cases of malaria and of dysentery, and the rainfall of the districts.

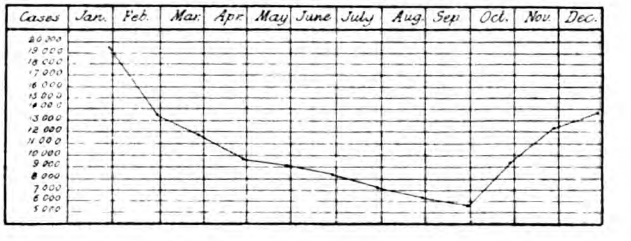
(*a*) *The Malaria in the East.*—Chart I. shows the

Chart I. *Total Diseases in the East, 1903.*



curve of total disease in the eastern portion of Ceylon. It will be noticed that it is similar to the curves of previous year. Highest in January and having a slight rise in May, it begins its proper rise in October.

Chart II. *Malaria in the East, 1903.*



The malarial curve, Chart II., shows that malaria is the disease which mainly produces the fluctuations in the curve of general disease in this part of Ceylon ; it is not responsible for the rise in May, and Chart III. shows that dysentery is the cause of this rise.

Chart IV.—The rainfall is quite different from preceding years, in which it has always risen to a maximum in November, while in this year its maximum is December. This alteration in the rainfall has altered

the December rise of malaria, and hence has altered the total disease curve in a way not shown in previous years. The sudden rise in December of the rain curve is associated with a slowing of the rise of the malaria curve, and even a fall of the total disease.

Chart III. *Dysentery in the East, 1903.*

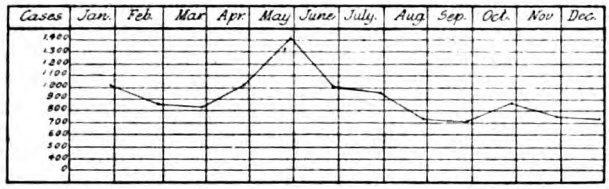


Chart IV. *Rainfall in the East, 1903.*

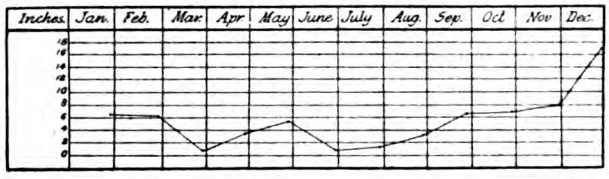

Chart V. *Total Diseases in the West, 1903.*

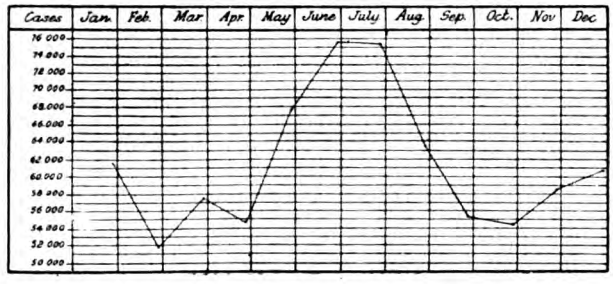
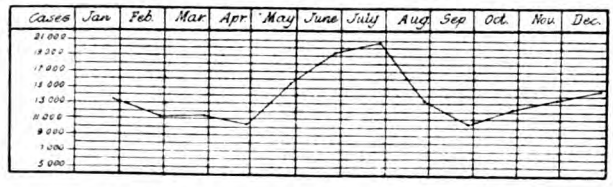


(*b*) *The Malaria in the West.*—Chart V. shows the total disease curve in the west, and is different from the previous years in having a large rise in June and July.

The rise is shown by Chart VI. (the malarial curve

Chart VI. *Malaria in the West, 1903.*



in the west) to be caused principally by malaria. This rise commences in May and reaches its maximum in June for total disease and in July for malaria. In causing this rise malaria is assisted by dysentery (Curve VII.), which commences its rise earlier, reaches its maximum in May, and falls through June without affecting the total disease curve because the malarial increase is marked, but its July fall causes a slight fall of the total disease curve, although the malarial curve continues to rise. Generally January is the great malarial month, and this is not so in 1903. The general malarial rise in 1903 is during and after the May rainfall, and the other rise is in November and December, after the October rainfall.

Chart VII. *Dysentery in the West, 1903.*

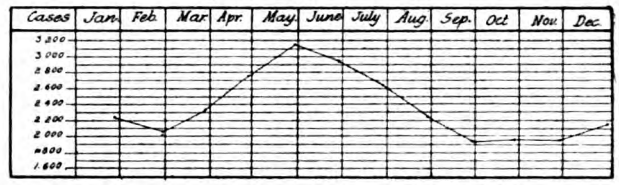


Chart VIII. *Rainfall in the West, 1903.*

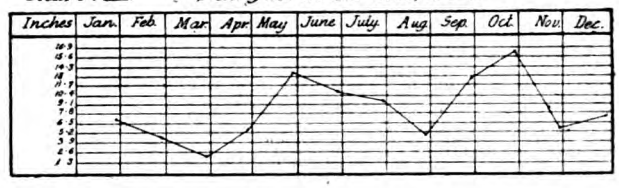

General Remarks.

It will thus be seen that in the eastern portion of the Island, affected by only the north-east rainfall, the malarial curve is related to the rainfall, and produces a powerful effect upon the general disease curve. The relationship to the rainfall is that the malarial curve, rising through October, November and December, reaches its maximum in January. This, I am sure, is related to the development of the Anopheles, for December and January are the great months for mosquitoes and January for malaria. The mosquitoes developing and increasing in number during and after the rain, spread the infection.

The relationship in the west is not so clear, as the influence of the two monsoons exists. Still, generally speaking, January represents the north-east influence, and May or June the south-west with regard to malaria.

IV.—General Sanitary Condition of the Colony and of the Chief Towns.

The general sanitary condition of the Island remains in much the same condition as last year. The same methods of disposal of sewage and refuse exist, and, though by no means satisfactory, are still far from bad when compared with other tropical countries. The water supply is often very good, and steps are being taken every year to remedy defects.

Colombo.—This city has had its sanitary staff considerably augmented recently. There are two specially qualified Medical Officers of Health, with a staff of Inspectors, in the employment of the Municipality. The disposal of sewage is the same as it has been for some years past, viz., the collection of solid matters for burial at various depôts, and the continuance of cesspits; the latter are being gradually filled up and closed. Colombo has contributed the largest number of cases of enteric fever, and in most cases the origin of the disease has been traced to contaminated water or milk.

The scavenging of the town is defective. Road sweepings and refuse are deposited over grass-fields

immediately outside the residential quarter; these harbour flies, which most likely carry infection. A proper cinerator or a series of cinerators should be erected by the Municipality for the destruction of all sweepings and refuse, and the heat generated should be available as a motive power for electric lighting. The dust in Colombo is a nuisance and a danger; there is too little watering and sweeping of the streets and of the collection and removal of the dust.

A beginning has been made towards introducing a water carriage system for sewage on Mr. Mansergh's scheme. The water supply of Colombo is deficient, but this is in process of being remedied. On the whole, Colombo is healthy for a tropical city. Much is being done in the way of improved sanitary measures, but a great deal is still required; *e g.*, the question of overcrowding, the removal of insanitary areas, surface drains, and cesspits.

The Colombo lake is a perennial source of anxiety, it is practically a receptacle for sewage, and during drought its level falls a good deal, exposing offensive muddy sides. It is also the breeding ground for myriads of small irritating flies. My idea is that it should be drained, and the area converted into an open space.

The notification of infectious diseases has been more satisfactory during the past year.

Kandy.—The general sanitary state of Kandy leaves considerable room for improvement. Several cases of enteric fever occurred in the town from insanitary causes. The drainage is imperfect. An improved scheme of drainage, it is reported, is under consideration. The water supply is sufficient and of good quality. The conservancy of the town has been improved, but several cesspits remain. Alleys are ill-ventilated, insanitary, and overcrowded.

Jaffna.—Jaffna is the only town in the Northern Province where sanitation is carried on to some extent, but even here a good deal of improvement is required. As it is the chief town of an important, populous, and rich Province, it should possess a local board or municipality.

Water for all purposes is obtained chiefly from wells, but the majority of them contain hard, brackish water, unfit for drinking. The water supply of Jaffna is most unsatisfactory, but a special public works department officer is at the present time surveying and making estimates for a better supply. I have not had any of the details sent to me.

Galle.—This town is in a fairly sanitary condition, the Fort especially showing considerable improvement after the closing of cesspits and the introduction of the dry-earth system in private houses. In the other divisions of the municipality much remains to be done in this direction. The water supply of the town is very defective.

Batticaloa.—The sanitary condition of Batticaloa is fairly satisfactory, but there is much room for improvement. A better system of drainage is required, but owing to the nature of the land, which is flat, this is a matter of some difficulty. The compounds should be kept cleaner, and swamps and marshy grounds drained and filled up. The water supply, which is drawn from wells, is ample, but some of the wells in the dry season are apt to fail.

Kurunegala.—The sanitary condition is not satisfactory. A water supply and drainage scheme are badly wanted; the latter and public markets will be taken in hand by the Local Board soon.

Anuradhapura.—The principal town of the North-Central Province formerly had a reputation for unhealthiness, but of recent years, owing to improved sanitary measures, the health of the inhabitants has wonderfully improved.

Badulla.—The water service is satisfactory. The drainage is defective. The scavenging was satisfactorily done. Public latrine accommodation is deficient.

Ratnapura.—The sanitary condition is not satisfactory. The drainage has not been improved. The water supply is said to be satisfactory.

V.—Medico-Legal.

Medico-Legal Duties.—During the year 1903, 230 analyses were conducted, of which 122 were judicial, 23 were samples of kerosine oil, 6 were samples of fuel oil, and 38 were samples of water, spirits, eau-de-cologne, arrack, cinnamon, oil, &c., from His Majesty's Customs, Local Boards, and the Railway Department, and 41 were samples of water conducted at the request of the Government. Of the 122 judicial analyses, 72 were undertaken for the detection of poisons and 50 for examination of stains. In the poisoning cases arsenic was detected in 5, arsenic and croton oil in 1, croton oil in 1, lead in 1, mercury in 4, copper in 1, magenta in 1, ammonia in 1, canabis indica in 13, opium in 4, opium and ganja in 1, atropine in 1, alcohol in 1, niyangala (*Gloriosa superba*) in 1, and in the rest of the analyses no poisons were detected.

A synopsis of the analyses for the year in a tabular form is herewith annexed:—

Synopsis of the Analyses for 1903.

VI.—Administrative Hospitals and Asylums.

The Government medical institutions are, as a rule, well built, either of stone or of brick, and contain large, airy wards, with plenty of cubic space and superficial area. The general type of hospital is an administration block in front with wards running at right angles to it, connected by covered corridors. The buildings consist of a ground floor only, and they occupy a good deal of space. The roofs are of red tiles, and the floors of cement concrete. The beds are of wood with cane bottoms, or of iron with copper spring mattresses; bedside tables are provided, and the fittings and equipment are serviceable, and, in some of the institutions, fairly up to date. All the hospitals have separate accommodation for women, and at many of them there are isolation wards.

In many of the hospitals there is no operating room. This defect is being attended to, and in some there are no residential quarters for the medical staff, nor accommodation for nurses. It is my object to improve the quality of the surgical instruments, and to gradually introduce modern appliances and aseptic furniture. A large number of good operating tables have been made locally and distributed to many of the institutions.

There is the great want in Colombo of a modern infectious diseases hospital. The present establishment consists of a series of cadjan huts, which have been yearly patched up since they were originally erected over twenty years ago. Their only advantage is that for sanitary reasons, when necessary, they can be destroyed by fire without much loss of money, for it is quite impossible to disinfect them, and their rough interior walls are most unsuitable for infectious wards from a hygienic point of view. I hope in the near future that a permanent hospital for infectious diseases on the pavilion plan, and with accommodation for paying patients, will be provided.

Native Attendants.—Male and female ward attendants are employed in the hospitals, who work under the directions of the nurses; they perform their duties fairly satisfactorily, but it would be well if a better class of attendant could be induced to take up the work, as many of those now employed are very ignorant and quite illiterate.

Nursing in Ceylon Hospitals.—The nursing in the Ceylon hospitals is not entirely satisfactory. Some of the out-station hospitals have no nurses; other hospitals are under-nursed. The question of improving this service is now under the consideration of Government. The nursing staff consists of—

4 European qualified nurses.
23 European Roman Catholic Sisters (untrained).
3 European Anglican Sisters (untrained).
1 European matron (untrained).
27 matrons (trained locally).
45 nurses (trained locally).

Three of the European qualified nurses are employed in the paying section of the General Hospital, Colombo. The fourth is the matron of the Lady Havelock Hospital. Two more European qualified nurses are expected in 1904. The Roman Catholic Sisters perform nursing duties in the general wards of the Colombo hospital and at Kurunegala. The Anglican Sisters are employed at the Kandy Hospital.

Two nursing schools for the training of young women exist at the Lady Havelock Hospital and the Kandy Hospital. The length of the course is two years, after which a certificate of proficiency is given to those who pass a satisfactory examination.

During the year 1903, 66 hospitals and asylums were in operation. The Immigrant Hospital at Puliyadirakkam was closed on December 31st, 1902, and the one at Pesalai was closed on March 1st, 1903. The lock hospital at Mahaiyawa was closed on December 31st, 1903. The Civil Hospital at Mulhalkele was closed in December, 1902, and was reopened in June, 1903, for the fever season.

Numbers Treated.—In the 32 Civil Hospitals, including the Lying in Home, there were 40,553 cases treated, with 3,433 deaths, being 3,420 cases and 265 deaths less than in the previous year. The daily average sick was 1,553·53, as against 1,652·51 in the previous year. In the eight Field Hospitals there were 4,105 cases treated, with 129 deaths, against 4,426 treated and 171 deaths during the previous year. The daily average sick was 179·59, against 179·46 in 1902. The number treated in the four immigrant hospitals was 1,318, against 1,855 in 1902; the deaths numbered 63, against 84 in the previous year. The daily average sick was 60·71, against 73·49 in 1902. In the twenty District Hospitals 13,081 cases were treated, against 14,928 in 1902. There were 1,859 deaths, against 2,510 in the preceding year. The daily average sick was 750·19, against 792·41 in 1902.

Surgical Operations. — At the various hospitals throughout the Island 2,172 operations were performed, with 72 deaths. The following is a summary of the operative work:—

Amputations:—	Cases.	Deaths.
Upper extremities	80	1
Lower extremities	27	2
Operations for cataract	73	—
Iridectomy	20	—
Radical cure for hernia	35	1
Radical cure for hydrocele	98	—
Hepatic abscess	36	12
Trephining of skull	30	2
Lithotomy, supra-pubic	6	1
Lithotomy, perineal	1	—
Laparotomy	17	7
Ovariotomy	11	3
Cæsarian section	1	—
Other eye operations	63	—
Other operations	1,674	43
Grand total	2,172	72

General Hospital, Colombo.—The total number of patients treated at this institution during the year was 14,606, with 1,138 deaths, against 16,035 cases and 1,101 deaths in the previous year. Of the total treated, 455 remained from the previous year and 14,151 were new admissions; 13,047 were discharged, and there remained 421 under treatment at the end of the year. The daily average sick was 486·82, and the percentage of deaths to total treated was 7·79. The institution consists of twenty-five wards and eight solitary rooms, and the number of beds is 425. An administration block, with quarters for the medical and nursing staff, is in course of construction, and will, when completed,

improve to a considerable extent the usefulness of the institution.

Paying Section, General Hospital, Colombo.—This consists of the wards "Planters'" (4 wards with 4 beds), "Anthonisz" (2 wards with 2 beds), "Passengers'" (8 wards with 8 beds), "Seamen's" (3 wards with 26 beds), "Clerical" (1 ward with 2 beds), and "Cargill's" (2 wards with 2 beds). The total number of patients treated in these wards during 1903 was 523, with 55 deaths, against 577 cases and 41 deaths in 1902. Of the total treated, 16 remained from the previous year and 507 were new admissions; 448 were discharged, and there remained 20 under treatment at the end of the year. The daily average sick was 26·34, against 27·61 in 1902, and the percentage of deaths to total treated was 10·51, against 7·11 in 1902.

Houses of Observation for Suspected Lunatics.—There are four institutions of this nature at Colombo, Kandy, Galle, and Jaffna, and into the first three were admitted for observation 323 patients, which, with 20 remaining from the previous year, made a total of 343, of whom 78 were transferred to the asylum at Colombo, 252 were discharged, 3 died, and 10 remained at the end of the year. There were no admissions to the House of Observation at Jaffna.

Lunatic Asylum, Colombo.—At the beginning of the year there remained 316 males and 167 females, total 483 cases. During 1903, 151 cases (103 males and 48 females) were admitted, the total number under treatment being 634 (419 males and 215 females). Of these, 49 males and 26 females, 75 in all, were discharged, and 39 males and 12 females, 51 in all, died.

The daily average was 488·37 (males 317·34, females 171·03), an increase of 6·92 as compared with the previous maximum average. This increase affects only the male division, which was already overcrowded.

The institution consists of 18 dormitories, 20 day-rooms and corridors used as day-rooms, and 134 single rooms. The water supply is drawn from the Labugama reservoir, which supplies the town. The quality is good. The Superintendent (Dr. J. B. Spence) complains of the inadequate supply of water; it is hoped that with the duplication of the main from Labugama this complaint will cease. There are 19 lavatories, 17 baths, and 19 latrines. The dry-earth system is carefully carried out. The number of patients secluded under lock and key was 8, and the number of times seclusion was resorted to was 190, and the longest duration in any single instance was six hours. There was one case of accidental injury to a patient by an attendant, another case of serious injury by a patient to another patient; other cases of injury have been rather unusually numerous, some being accidental in origin and others being due to the action of fellow-patients. No case of suicide occurred during the year. Such patients as are well enough are given daily exercise, while others are confined to the airing courts. Outdoor sports (cricket and tennis), as well as indoor games (cards, bagatelle, musical instruments, &c.), are provided. A gramophone was purchased last year from industrial funds. A library is in existence, and those who can read are regularly supplied with books and papers, but it has not been availed of to any large extent. The inmates of the Asylum are employed in gardening, trade, housework, &c, and the proceeds of their industry is formed into a fund, which at the end of the year amounted to Rs. 18,900·40.

The Lunatic Asylum has reached the limit of its accommodation, overcrowding is constant, and the question of providing more buildings is a pressing one.

Leper Asylum, Hendala.—The Leper Asylum received 136 patients for treatment during the year, which, with 311 remaining from the previous year, made the total 447. The daily average in the Asylum was 290·83. Of the total treated, 75 left, of whom 48 absconded and were reported to Government Agent and Police, and subsequently arrested and brought back to the Asylum. Nine lepers were discharged and permitted home isolation, subject to the regulations framed under the Leper Ordinance. One Tamil immigrant was sent back to his village in South India. There were 83 deaths, giving a percentage of 18·56 to total treated. Two hundred and eighty-nine cases remained under treatment at the end of the year.

De Soysa Lying-in Home.—The total number of patients treated at this institution during the year was 818, against 737 in 1902, 499 in 1901, and 163 in 1890. Of these, 775 were discharged cured, 2 removed by relatives, 5 transferred to the General Hospital, 17 died, and 19 were remaining under treatment at the end of the year. The daily average sick was 18·52. The percentage of deaths to total treated was 2·12, against 1·25 in 1902, ·80 in 1901, and 3·08 in 1890. The popularity of the institution is daily increasing, specially with the Mohammedan patients, whose admissions are increasing year by year. The increase of this caste from 20 in 1902 to 32 in 1903 is a substantial one.

The following operations were performed during the year:—

Class.	Division.	Subdivision.		
Forceps	Difficult	Brow	3	
		Head	115	
	Complex	Twins	4	
		Prolapse of cord	4	
	Preternatural / Compound	Head and hand	10	
				136
Version, podalic	Complex	Placenta prævia	6	
		Transverse	14	
	Premature birth	Small head	4	
				24
Craniotomy	Difficult	Hydrocephalus (head)		3
Evacuation of uterus	Abortion	Removal of placenta and ovum		20
Separation and removal of placenta	Complex	Morbidly adherent placenta		10
Acceleration of labour by water bags	Complex	Placenta prævia		6
Abdominal section and Baer's operation				1
Puerperal eclampsia				6
		Total		206

In the Lying-in Home 23 pupil midwives receives training in 1903, of whom 17 obtained certificated

after passing a satisfactory examination. A scheme to train selected pupils from all provinces has been adopted, and it is hoped that it will be the means of introducing European midwifery into the villages.

Lady Havelock Hospital.—In this institution 1,137 patients were treated, against 1,072 in 1903. Thirty-one remained from the previous year, and 1,106 were new admissions. The daily average sick was 34·06. Nine hundred and ninety-four patients were discharged. There were 111 deaths, and 32 remained under treatment at the end of the year. Of the 1,137 patients, 351 were children (124 boys and 227 girls). There were 49 operations performed, with 3 deaths. The number of cases of diseases peculiar to women was 164, as compared with 147 in 1902. The total number of Mohammedans was 83. There were 12 paying patients, as compared with 10 in 1902. Of these, 6 were Europeans, 2 Burghers, 1 Tamil, 2 Sinhalese, and 1 American.

Police Hospital, Colombo.—Eight hundred and forty-five patients were treated in the Police Hospital, of whom 838 were discharged after treatment, 1 died, and 6 remained at the end of the year. The daily average sick was 13·35. At the outdoor dispensary of this hospital 2,200 persons were treated during the year, who paid 2,469 visits.

Grenier Eye, Ear, and Throat Infirmary.—At this institution 6,602 cases were treated during the year, against 4,927 in the previous year. The contributions during the year amounted to Rs. 126·20, and were of a purely voluntary nature.

Branch Hospitals.—Colombo, Kandy, and Galle are provided with a special hospital for the treatment of women suffering from venereal diseases. The total number of new cases admitted was 289, which with 18 remaining from the previous year make a total of 307, against 371 in 1902. Of these, 290 were discharged, 2 died, and 15 remained at the end of the year. Of the 307 females in the three Branch Hospitals, 30 were treated for primary syphilis, 53 for secondary syphilis, 72 for tertiary syphilis, 4 for inherited syphilis, 113 for gonorrhœa, and the rest for other diseases, the result of venereal poison. The patients seek voluntary admission.

Jail Hospitals and Sick Prisoners.—The number of prisoners admitted to the different jails in the Island was 13,797. The average daily strength of prisoners was 2,784. The number treated in the jail hospitals during the year was 4,396, against 5,363 in the previous year. The total deaths numbered 73, against 117 in 1902.

RETURN OF DISEASES IN JAIL HOSPITALS FOR 1903.

Diarrhœa	Cases	850
	Deaths	7
Malarial fever	Cases	796
	Deaths	3
Enteric fever	Cases	26
	Deaths	4
Other fevers	Cases	34
	Deaths	—
Injuries	Cases	219
	Deaths	—
Leprosy	Cases	2
	Deaths	—

The following table gives the number of admissions, number of deaths, average strength, death-rate to admission to hospitals, and to average strength for the past four years :—

Year	Admissions to Hospitals	Number of Deaths	Average Strength of Prisoners	Death-rate to Admissions	Death-rate per 1,000 of Average Strength
1900	4,465	102	2,515·14	2·28	40·55
1901	4,638	112	2,752·71	2·41	40·69
1902	5,363	117	2,656·40	2·18	44·05
1903	4,396	73	2,784·00	1·66	26·21

Kanatta Infectious Diseases Hospital. — At this institution 11 cases of infectious diseases remained from the previous year, and 316 were admissions, making a total of 327. Of these, 303 were discharged cured, 4 died, and 20 remained. The death-rate was 8·50 per cent., against 8·77 per cent. in 1902. Of the 327 patients, 14 were treated for small-pox, 203 for chicken-pox, 89 for measles, 5 for whooping cough, 15 for mumps, and 1 was under observation for cholera. Of the 14 cases of small-pox, 2 died. There were no admissions into the segregation hospital at Borella.

The following two institutions are not entirely supported by, but receive a large subsidy from, the Government :—

(1) *The Friend-in-Need Society's Hospital at Jaffna.*—The Friend-in-Need Society's Hospital at Jaffna received 2,094 patients, which with 73 remaining from the previous year made a total of 2,167. Of these, 2,020 were discharged, 85 died, and 62 patients remained at the end of the year. At the outdoor dispensary of this institution 10,575 persons were treated during the year, who paid 20,328 visits.

(2) *The Victoria Home for Incurables, Colombo.*—The statement of admissions and deaths is annexed :—

Disease	Number Remaining on December 31, 1902	Yearly Total, 1903		Total Cases Treated	Remaining at the End of December, 1903
		Admissions	Deaths		
Paralysis	36	8	3	44	41

Total Deaths.—The total deaths numbered 5,622, against 6,560 in 1902, showing a decrease of 938. A table showing the death-rate in the various hospitals and asylums in the Island for the year as compared with the last year is annexed. For purposes of comparison the death-rates among the mixed races and Malabars have been shown separately :—

Hospitals	Mixed Races		Malabars		Total	
	1902	1903	1902	1903	1902	1903
Civil	5·59	6·12	16·01	15·86	8·18	8·47
Field	3·22	3·08	9·97	3·87	3·86	3·14
Immigrant	3·71	2·86	6·37	9·00	4·52	4·77
District	4·60	4·74	21·97	19·52	16·88	14·21
Asylums	7·49	10·26	8·37	10·80	7·61	10·33
Total ..	5·26	5·97	18·25	17·13	9·87	9·3

The percentage of deaths to cases treated in the Civil Hospitals showed a slight increase among the mixed races, and a slight decrease among the Malabars. In the Field Hospitals there was a slight decrease among the mixed races, and a decrease of 6·10 among the Malabars. In the Immigrant Hospitals the decrease among the mixed races was ·85, but among the Malabars there was an increase of 2·63. In the District Hospitals there was a slight increase among the mixed races, but among the Malabars there was a decrease of 2·45. Taking all the hospitals and asylums together, there was a slight increase in deaths among the mixed races and a decrease of 1·12 among the Malabars. The percentage of deaths to total treated was 9·3, against 9·87 during the previous year.

Hospital Accommodation.—This was generally sufficient; occasionally some overcrowding took place. This remark especially applies to the Leper Asylum at Hendala, for the extension of which steps are being taken, to the Lunatic Asylum, and to the General Hospital, Colombo.

Water Supply—The water supply—with the exception of the following institutions: Matale, Mannar, Galle, Chilaw, Nikaweratiya, Balangoda, Trincomalee—was reported to be good, pure, wholesome, and abundant. Water for drinking purposes is, as a rule, boiled and filtered before use. Water supply schemes for Nanu-oya, Balangoda, and Tillicoultry are under consideration.

Bathrooms.—All hospitals are provided with separate bathrooms for males and females, and furnished with tubs, which are filled with hot or cold water, according to the requirements of the patients. Patients who can help themselves, however, prefer to bathe in streams, where there are such adjoining a hospital.

Drains.—There are no covered drains. The drains are all surface ones for carrying away the ward washings, rain, and storm water.

Sewage.—The conservancy of the latrines is entirely on the dry-earth system, the excreta being removed daily and buried, or incinerated at some distance from the Hospitals. Doulton's earthenware squatting plates have been introduced in some of the hospitals.

Inspection.—The hospitals were all inspected either by me or the Colonial Surgeons of the respective Provinces. The number of these visits of inspection and the official designation of the visitors will be found given in the return of each institution. The books were produced when called for, and were generally found complete and made up to the date of examination. The reports of inspection by the Colonial Surgeons, as well as those by me, were forwarded to Government when necessary.

Food Supply.—The provisions for the various hospitals were supplied by purveyors on contract approved by Government. The system works satisfactorily. The Medical Officers in charge of the respective hospitals examine the food before it is served out to the patients, and reject such articles as do not come up to contract sample.

Dispensaries.—Four hundred and sixty-seven dispensaries, including branch institutions and visiting stations, were in operation. Of these, 297 were Civil, 44 District, and 126 Estate. They are distributed as follows: In the Western Province 33, Central 62, Northern 44, Southern 36, Eastern 32, North-Western 36, North-Central 39, Province of Uva 30, and Province of Sabaragamuwa 29, and on estates 126. In the Civil and District dispensaries there were treated 921,392 persons who paid 1,434,250 visits, against 975,160 persons who paid 1,499,227 visits in 1902.

Port Duties and Immigration. — The number of vessels which arrived at the Port of Colombo was 3,077, against 2,802 in 1902, 2,617 being steamers, 1 sailing ship, and 459 native craft. The number of native traders was 66,068 and coolies 47,858, against 60,672 and 33,760 in the previous year. Dr. Woutersz took up the duties of Senior Port Surgeon on October 10th, 1903.

Ragama Camp.—The number of coolies who passed through the camp during 1903 was 46,478, against 34,280 in 1902. There was only one fatal case of cholera there during the year. Of the number of coolies who passed through the camp, 2,493 were vaccinated, and the rest either had marks of successful vaccination or of small-pox.

De Soysa Bacteriological Institute.—Dr. S. C. Paul, F.R.C.S., was in charge of this institution till December 30th, 1903, when Dr. Aldo Castellani, M.D. (Florence), assumed duties as Director. The fees recovered amounted to Rs. 325·50, against Rs. 298 in the previous year.

Ceylon Medical College.—The College, in charge of Dr. Chalmers, M.D., F.R.C.S., contains lecture halls, laboratories for chemical physiology and pathology, physiology, biology and pathology, dissecting room, offices, photographic rooms, a museum and Colonial Medical Library, and a separate building for lady students containing sitting-room, lavatory, and special dissecting room. An extension is proposed for 1905 for students' common room, lecturers' lavatories, materia medica museum, a lecture hall, and a suite of laboratories for the Public Analyst.

From October, 1904, the new chemical lecture hall and laboratory and the two physical laboratories at the Technical College will be used by the students of the Medical College. A Professor of Chemistry is being obtained for the Medical College from England, and should arrive before October, 1904. During the year 11 new medical students, 4 apothecary students, and 1 casual student entered the College. There were 96 medical, 32 apothecary, and 1 casual student at the end of the year. The total fees amounted to Rs. 17,260·50, which is an increase of Rs. 1,347·35 upon the fees of 1902.

The Government at my suggestion allowed the expenses for a post-graduate course at the Medical College for a fortnight's duration in April, for officers of this Department stationed at a distance from Colombo, to familiarise themselves with some of the recent advances made in Medical and Surgical Science. Thirteen Medical Officers attended. It is hoped that this course will be followed by similar ones each year.

Civil Medical Stores.—Dr. Owen Johnson was in charge of this institution as Acting Medical Superintendent. Mr. A. D. Cotton is the Chief Storekeeper. The drugs, chemicals, and instruments received from England amounted to Rs. 178,473·81, from India Rs. 4,320·62. The cost of articles purchased from the Government Stores and the local market for the preparation of drugs in the Medical Stores came to Rs. 5,734·15, while the cost of repairing surgical instruments amounted to Rs. 50·50, and that of transport and postage to Rs. 3,943·22; extra service, petty expenses and contingencies to Rs. 685·54; the sale of medicines to Government Departments and others, Rs. 2,343·68; sale of medicines to planters, Rs. 1,683·15. The sale of unserviceable articles realised Rs. 90·62, and the value of the surgical instruments lost and paid for by the officers of the Department amounted to Rs. 192·28. The cost of quinine, fever powders, &c., issued to Government Agents and others free of cost was Rs. 2,984·67.

Strength of the Medical Department.—The strength of the Medical Department was as follows: 1 Principal Civil Medical Officer and Inspector-General of Hospitals, 1 Assistant Principal Civil Medical Officer, 1 Registrar of the Medical College, 1 Director, Bacteriological Institute, 7 Colonial Surgeons, 1 Superintendent of the Lunatic Asylum, 1 Surgeon in charge of the General Hospital at Colombo, 2 Medical women, 23 Assistant Colonial Surgeons, 27 Deputy Assistant Colonial Surgeons, 40 Sub-Assistant Colonial Surgeons, 15 Probationer Sub-Assistant Colonial Surgeons, 4 Health Officers, 245 Apothecaries, 1 Chief Medical Storekeeper, 1 Chief Inspector of Vaccination, 6 Inspectors of Vaccination, and 108 Vaccinators.

Estates Branch.

During the year 1903 there were 1,798 estates scheduled to 33 districts and 31 sub-districts, with 20 District Hospitals and 29 District Dispensaries and 13 Civil Hospitals and Dispensaries.

To attend to the medical wants of the above the following officers were employed: Deputy-Assistant Colonial Surgeons 15, Sub-Assistant Colonial Surgeons 10 (1 vacant), and Apothecaries 28.

During 1903 there were 9,158 estate labourers treated in the District Hospitals and Civil constituted District Hospitals, against 10,995 in 1902. Of these 1,812 died, a death-rate of 19·78 per cent. Of the mixed races 14,693 were treated, of whom 884 died, a death-rate of 6·01 per cent.

In the Civil Hospitals worked partly as District Hospitals the death-rate of estate labourers was 20·61 per cent., whilst in the District Hospitals it was 19·45 per cent. The highest death-rate (27·8 per cent.) among the estate labourers occurred in the District Hospital at Haputale, and the lowest (8·31 per cent.) in the Civil Hospital at Balapitiya. The admissions into the former were 241, into the latter 36. In the Civil Hospital, Mulkalkele, which was open only during the fever season, there were no deaths among estate labourers.

The total number of days the estate labourers stayed in hospital was 243,125, an average of twenty-six days. Of these, 169,056 were paid for by the estates, the rest being charged to the fund. The total number of days mixed races stayed in District Hospitals was 176,033, an average of twelve days.

The total number of estate labourers treated at the out-door dispensaries was 73,455. The total number of estate labourers treated on estates was 25,265.

The total number of births reported from estates was 11,637, of which 5,778 were males, 5,609 were females, and 250 were still-births.

The number of deaths reported from estates was 8,224, of whom 4,028 were males, 4,192 were females, and in 4 cases the sex was not stated.

The expenditure under the Medical Aid Ordinance amounted to Rs. 523,163·72, including exchange compensation, and receipts to Rs. 326,535·91, derived from the following sources: Export duty Rs. 140,022·09, hospital charges for treatment of coolies Rs. 54,784·90, recovered for visits paid to estates Rs. 20,660, sale of unserviceable and superfluous articles Rs. 205·62, medicines sold to superintendents of estates Rs. 1,745·99, medicines sold in bulk to superintendents of estates and prescriptions compounded Rs. 10,253·59, dispensary collections Rs. 2,273·82, cost of maintenance, medicine, and funeral expenses of other than estate labourers Rs. 92,680·87, recoveries for maintenance of others Rs. 3,909·03. The net expenditure was Rs. 196,627·81. One hundred and twenty-six dispensaries are now established in the planting districts. The gross expenditure was—

	Rs.	c.
Civil Branch	1,294,925	85
Estates Branch	523,163	72
Total ..	1,818,089	57

And the net expenditure was—

	Rs.	c.
Civil Branch	1,064,408	73
Estates Branch	196,627	81
Total ..	1,261,036	54

No. 6.

FEDERATED MALAY STATES.

Medical Report on the State of Pahang for 1903.

By S. LUCY, State Surgeon, Pahang.

In-Patients.

(1) During the year 2,008 patients were treated in the wards of the various hospitals, as compared with 1,894 in the previous year. The admissions at the Bentong Hospital, which numbered 793 as against 421 in 1902, entirely account for the total increase of in-patients; at all other hospitals the numbers have fallen off, particularly is this the case at Raub and Kuala Lipis. The small number of patients seeking admission at these hospitals is attributable to the closing down or great reduction in the labour forces of the more important neighbouring mines, rather than to any betterment of the public health. At Bentong there has been much overcrowding, and the want of accommodation has caused some inconvenience and not a little suffering; numbers of patients were refused admission, and others have been discharged before they were fit to return to work in order to make room for grave cases demanding immediate attention. Increased ward space is being provided.

(2) The mean mortality amongst the in-patients was 11·05 per cent., as against 12·14 per cent. in 1902. The highest death-rate occurred at Bentong—viz., 15·48—but these figures compare very favourably with those of last year, when the death-rate was 25·70 per cent. The serious condition of large numbers of the patients admitted to this hospital may be deduced from the fact that no less than 43 patients died within forty-eight hours of admission. If these are excluded, as they fairly may be in computing the death-rate, the mortality at Bentong is reduced from 15·48 to 10·32. The mean death-rate for all hospitals, exclusive of cases dying within forty-eight hours of admission, was 7·91.

Out-Patients.

(3) Thirteen thousand eight hundred and forty-nine visits were made to the out-patient department during the year; these figures include 8,428 new cases and 5,421 repetitions, as against 7,620 new cases and 4,105 repetitions in 1902.

(4) The Malays are very ready to accept European medicaments and methods of treatment when these are brought to their doors; and, though shy of seeking admission or treatment at the station hospitals, they are eager enough to submit to examination, and will clamour for drugs when a visit is made to their kampongs. Severe forms of skin disease and bowel complaints due to intestinal parasites are very common, and cause much distress and permanent impairment of health to the native children. The majority of these complaints are very amenable to treatment, but it is at present impossible to bring this treatment within easy reach of the widely distributed Malay population of the State.

Prevalent Diseases.

(5) Malarial Fever.—This disease accounts for the greatest number of admissions to the wards; most of the cases are benign in type, and respond readily to treatment; the mortality occurs mainly amongst the chronic malarial cachexias. The intense forms of malignant infection are uncommon; 607 cases of malarial disease, with a mortality of 5·42, points to the conclusion that malaria is not by any means the most formidable of tropical diseases met with in Pahang, though the above figures do not convey a correct impression of the total damage to the general health caused by the malarial parasite, principally for two reasons—firstly, because Malays rarely come for treatment for this disease, they regard two or three attacks of malaria each year as a matter of course and unavoidable; and secondly, because repeated attacks of malaria are common and produce a cachexia which renders the subject particularly liable and non-resistant to any intercurrent disease to which he may fall a victim.

(6) At Lipis the police force has usually suffered somewhat severely from malaria, and during 1902 there were 116 admissions to hospital from the force from that disease. In July last a ration of 5 grains of quinine was given daily, and in August each man was, in addition, provided with a mosquito-net. From January 1st, 1903, to the date upon which the above-mentioned precautions were taken—viz., August 15th—there were 47 admissions for malaria, and from this date to December 31st, 18 only, or a total for the year of 65 as compared with 116 in the preceding year; the strength of the force in the Lipis command being practically the same for both years.

(7) Bowel Complaints.—Dysentery and diarrhœa produce, as usual, a heavy mortality—viz., 235 cases and 67 deaths, as against 241 cases and 57 deaths during 1902. The chronic forms of these diseases are very fatal and difficult of treatment; the native rarely has sufficient sense or power of self-denial to submit to the severe regimen in diet which is indicated in these cases.

(8) Beri-beri.—The case mortality from this complaint is very high, 157 cases and a mortality of 22·22 per cent., as compared with 144 cases and a mortality of 30·35 per cent. in 1902. Of the 35 fatal cases 21 occurred in the Bentong Hospital, which presents a case mortality of 31·81 per cent. from this disease. The cases occur almost entirely amongst the tin-mining population.

(9) PHTHISIS, with 48 cases and 20 deaths as compared with 26 cases and 12 deaths last year, would seem to be on the increase. It runs a rapid course in this moist climate, and, once acquired, a fatal termination can be predicted, with the very free ventilation that obtains, at any rate amongst the rural and mining population. I do not believe that any serious spread of the disease need be feared; it is, generally speaking, the opium-sodden Chinaman, who spends most of the day and night in a dark, hot, and ill-ventilated barrack, who contracts and rapidly succumbs to this disease.

INFECTIOUS DISEASES.

(10) No cases of grave infectious diseases were treated at any State hospital during the year; of the main infectious disorders, there were 8 cases of influenza, 1 chicken-pox, and 1 mumps.

(11) Early in the year small-pox appeared nearly simultaneously at the coast districts of Kuantan and Endau. The outbreak at Kuantan was quickly got under, and resulted in 23 cases and 2 deaths. The epidemic at Endau proved more troublesome, and the disease was not stamped out until September; it was of virulent type, and, of the 152 cases that came under treatment, 34 proved fatal.

VACCINATION.

(12) The total number of vaccinations performed during the year amounted to 2,231; of this number 502 were unsuccessful. The majority of these vaccinations were done in the Endau district during the small-pox epidemic, and include re-vaccinations and the inoculation of protected persons. The District Surgeon further accounts for a number of failures to a batch of badly-prepared lymph-tubes. As a rule, the Saigon lymph can be relied upon, and is far more efficient than the English prepared lymph.

An enactment providing for compulsory vaccination is under consideration, and, it is to be hoped, will soon become law. The subjoined table gives the number of vaccinations during the past six years:—

Year.	Vaccinations.
1898	1,364
1899	7,619
1900	3,588
1901	2,874
1902	2,499
1903	2,231

GENERAL.

(13) Through the courtesy of the managers of the mining companies and the medical officers or dressers in charge at Sungei Lembing, Blat and Penjum, I am able to publish the following figures relating to the hospitals or dispensaries at Sungei Lembing, Blat and Penjum:—

	Cases treated, in-patients.	Deaths.	Out-patients.
Pahang Corporation's Hospital at Sungei Lembing... ...	825	127	3,220

(14) At the Blat Mines a hospital was opened early in the year, and a dresser placed in charge. An average daily number of about 25 patients has been maintained.

(15) At the Penjum Dispensary 567 cases received treatment during the year.

(16) A Government hospital is again to be built at Kuantan. It will be commenced, and, it is hoped, completed, before the end of 1904. The mining population in the Blat and Lepar districts is increasing rapidly, large numbers of sinkehs are imported, and these suffer severely from fevers and beri-beri during the wet months of the north-east monsoon.

(17) An enactment to provide means for the prevention of the introduction and spread of contagious and infectious diseases became law in the latter end of the year.

SANITATION.

(18) The sanitary conditions of the townships have not materially altered during the year; some concrete drains have been put in at Raub, and a swamp at Lipis has been partially drained.

(19) The insanitary condition of Bentong village and of some more important works for its improvement has been the subject of a special report to Government.

(20) Raub is the only station at which there is a water supply not obviously liable to sewage contamination.

(21) At Kuala Lipis the European community is still dependent for water for all purposes on the Jelai and Lipis rivers, both of which are the public sewers of the native population.

Medical Report on the State of Negri Sembilan for 1903

By J. SHIPLEY PART, M.D.

Acting State Surgeon.

(1) There has generally been an increase of in-door patients and a decrease in out-door during the year—the total together showing 287 increase in both classes—the relative figures being for 1902, 11,899, and for 1903, 12,186.

(2) The year showed a decreased rainfall with several spells of drought. The diarrhœa and dysentery were about the same as in the previous year.

(3) The usual state of things was observed—namely, that diarrhœa and dysentery were worse in dry weather, tending to disappear on the occurrence of heavy rains.

(4) The diseases showing the largest numbers of admissions are as follows in order of occurrence, the highest being (1) beri-beri, (2) ulcers, (3) fever, (4) dysentery, (5) diarrhœa.

(5) The sanitary conditions are not ideal anywhere, since all excreta is disposed off in the soil, water supply being almost entirely from wells.

In Seremban the drainage system badly wants overhauling in places, but this takes time and is in hand.

(6) Something has been done during the year, but much remains in the way of filling up mining holes, borrow pits, &c., in the neighbourhood of the town. Holes continue to be made wherever roads are built on the flat, and they are not drained.

VACCINATION.

(7) There were 2,373, of which 874 were done in Johol, a sub-district of Kuala Pilah, a collection of kampongs about which more below.

It is exceedingly difficult to obtain proper protection in some districts owing to the ignorance and prejudice of the outlying-kampong Malay, although in other

places quite contiguous they fully appreciate its advantages.

SMALL-POX.

(8) There were four outbreaks of this disease in the State during the year—at Johol 270 cases, Ayer Kuning 49, Rembau 8, Seremban 1 case.

There is one point to which attention should be drawn, and that is an important one in discussing the Johol outbreak—namely, at the commencement in June, it was decided by the Medical Department to isolate cases and contacts, but this was not allowed by the Government, and the Medical Department was instructed to rely solely on vaccination. That this measure when completely carried out will prevent outbreaks is true, but when in a scattered jungle population there is widespread objection to it, this proper carrying out is next to impossible, as many of the people disappear when the vaccination officer appears on the scene. The people wander about from kampong to kampong and so variola is spread broadcast wherever a few cases occur; this cannot be stopped without isolation, and to do so efficiently requires proper buildings with staff.

(9) Diarrhœa and dysentery, the usual scourges of the country, among the Indian population at least, shows no increase, though 797 more in-patients were treated than last year, and this in spite of the large numbers of men imported by the Federated Malay States Railways.

This result I attribute to the greater care exercised in regard to their food supplies and housing, also to the greater promptitude with which they are brought under treatment The mortality in diarrhœa shows a mortality of 28 per cent. as against 42 per cent. for the previous year; dysentery 29 per cent. against 40 per cent. of 1902.

(10) Beri-beri shows an increase of cases (total 1,141) with a mortality of 7·09 per cent. as against 881 cases in 1902, mortality 9·1 per cent.

WORK OF THE DEPARTMENT GENERALLY.

(11) On September 5th the State Surgeon left on long leave, the District Surgeon acting for him, he being relieved by Dr. Milne, an assistant to the Institute for Pathological Research, Federated Malay States.

(12) Every effort was made by the Government during the year to obtain more assistant-surgeons, but without success, and the department is consequently undermanned as usual, there being five vacancies out of six appointments for assistant-surgeons.

(13) The remedy for this is hard to see. To remedy it promptly, the only thing to do appears to be to increase the inducements in the shape of pay, to begin with.

(14) In time it can be done by educating selected boys who should be picked for smartness from the whole F.M.S., and recommended by the school authorities, but if this is to have continued success the allowance $25 per mensem during their college course will have to be increased.

(15) One man sent to India was a married senior dresser of long service, able and trustworthy; he could, of course, not exist on the pittance given him and had to return.

(16) The European and second-class wards were opened in the middle of the year, and 15 patients treated there with one death.

(17) The one nurse we have has been a great boon, and I should like to see another appointed to provide for outside nursing and night work; this would encourage materially the willingness of officers and their families to go into hospital for treatment.

(18) The total number of in-patients treated shows an increase from 4,453 in previous year to 5,250.

(19) There were 29 operations done during the year, including a large proportion of major ones.

TOTAL CASE MORTALITY.

(20) For all hospitals, 7·8 per cent.; the highest being at Tampin and the lowest at Port Dickson. At the Seremban hospital, the gross mortality was 8·1 per cent. and the net (deducting those dying within forty-eight hours) 5·7 per cent.

NATIONALITIES.

(21) Of the in-patients 66 per cent. were Chinese, 23 per cent. were Tamils, 4 per cent. were Malays, 3 per cent. were Sikhs.

PARTICULAR HOSPITALS—SEREMBAN GENERAL AND PAUPER HOSPITALS.

(22) (Admissions 2,771, mortality 8·2 per cent.) An increase of 632 admissions and a decrease of mortality of nearly 50 per cent.

23. Mr. R. Van Geyzel acted as assistant-surgeon during the year.

SEREMBAN GAOL INFIRMARY.

(24) Sickness rate, 74 per mille against 55 last year; mortality of cases treated 5·3 per cent. against 10·8 last year. In all four prisoners died; one from diarrhœa, one dysentery, one pulmonary phthisis and one undiagnosed.

The District Surgeon and a dresser from the pauper hospital visited the infirmary daily.

BERI-BERI HOSPITAL, PORT DICKSON.

(25) (Admissions 263, mortality 4 per cent.) Admissions increased by 40, and a slight increase of mortality, which last year was 3·96 per cent.; 38 per cent. of the deaths in this hospital were from dysentery. Dresser in charge, A. P. Koek.

JELEBU HOSPITAL.

(26) (Admissions 688, mortality 7·9 per cent.) An increase of 105 admissions; and a decrease of mortality, which was 9·64 last year. Dresser in charge, T. Kanapathipillay.

KUALA PILAH HOSPITAL.

(27) (Admissions 626, mortality 8·8 per cent. There has again been a decrease of admissions to this hospital—97 less than last year; and an increase to the mortality, which was 4·83 in 1902. Mr. P. La Brooy acted as assistant-surgeon in charge of this hospital during this year.

TAMPIN HOSPITAL.

(28) (Admissions 492,mortality 9·7 per cent.) There has been an increase of admissions in this hospital by 73. The mortality remains about the same. Mr. H. G. Copcult, assistant-surgeon, was in charge during the year.

PORT DICKSON DISPENSARY.

(29) At this institution 510 cases, including re-visits, were attended to as out-patients against 466 in 1902; and 680 in 1901.

Medical Report on the State of Selangor for the Year 1903.

By E. O. A. TRAVERS.

State Surgeon.

Population.

The estimated population of the State on December 31st, 1903, was 216,923. Two thousand two hundred and two births and six thousand six hundred and eighty-nine deaths were reported during the year.

The birth-rate calculated as for the population of the State at the end of the year was 10·151 per mille, and the death-rate 30·835 per mille.

Meteorological Condition of the Seasons.

The total rainfall registered at Kuala Lumpur was 89·89 in., as against 116·40 in. 1902.

As is usually the case, the heaviest rainfall occurred in the last three months of the year.

The month of July was an exceptionally dry one, only 0·20 in. having been recorded, as against an average for the last twenty-five years of 3·94 in.

The mean temperature was 80·1° F., as against 81° F. in 1902. The maximum temperature registered at Kuala Lumpur was 93° F. and the minimum 68° F.

Prevalence of Sickness and Relative Mortality in Different Seasons.

No special effect of season on the health of the inhabitants or on the relative mortality was noted.

Number of Patients Treated in the Various Hospitals and Infirmaries.

The number of patients treated, with deaths and death-rate during the last five years, is shown in the following table :—

Year.	No. treated.	Deaths.	Death-rate.
1899	12,371	1,437	11·61
1900	17,963	2,419	13·43
1901	21,351	2,797	13·10
1902	18,173	2,087	11·48
1903	14,425	1,872	12·97

There has been a reduction of 3,748 in the number of cases treated as in-patients as compared to the total for 1902. This is mainly due to the closing of the railway hospital at Kajang, where 1,822 patients were treated in 1902, the vastly improved health of the prisoners in the Pudoh Gaol, where only 295 cases were treated, as against 1,169 in 1902, and a reduction of 686 in the number of cases treated in the Ulu Selangor Hospitals.

The number of deaths occurring in all hospitals was 1,872, as against 2,087 in the previous year.

This is the lowest number of deaths in hospital since 1899, which is satisfactory in view of the steady increase in the population of the State.

The death-rate for all hospitals was 12·97 per cent., as against 11·48 per cent. in 1902.

Two hundred and forty-nine patients were admitted in a practically moribund condition and died within forty-eight hours of coming to hospital.

Most of these patients were brought in by their friends in order to avoid the expense and inconvenience of burial.

Prevailing Diseases.

The following diseases caused the greater amount of sickness and mortality :—

Disease	No. Treated		Deaths		Death-rate	
	1902	1903	1902	1903	1902	1903
Malarial fevers ..	2977	1980	174	153	5·84 %	7·72 %
Beri-beri	2673	1912	325	351	12·15 ,,	18·35 ,,
Diarrhœa.. ..	1515	1074	528	359	34·85 ,,	32·42 ,,
Dysentery ..	973	638	320	229	32·86 ,,	35·89 ,,
Pulmonary diseases	850	811	241	266	28·35 ,,	32·78 ,,

Bowel Complaints.

I am glad to be able to report a large reduction both in the number of cases treated and the number of deaths from this form of disease.

The figures for the last three years are as follows :—

Year.	Total treated.	Deaths.	Death-rate.
1901	3,826	1,143	29·8 per cent.
1902	2,488	848	34·0 ,,
1903	1,712	588	34·3 ,,

Improvements in water supply, drainage and general sanitation are, I consider, mainly responsible for the marked decrease in the number of cases of this group of diseases.

Malarial Fevers.

The returns relating to malaria also show very marked improvement.

Year.	Total treated.	Deaths.	Death-rate.
1901	5,445	322	5·9 per cent.
1902	2,977	174	5·8 ,,
1903	1,980	153	7·7 ,,

The great reduction in the number of cases of malaria occurring in the State may be attributed to a very great extent to the sanitary work carried out by Government at Klang and Port Swettenham.

There is little doubt but that in former years the Klang district acted as a distributing centre for malaria, persons suffering from the disease carrying it about the State, and through the agency of mosquitoes giving the disease to others, and often introducing it into districts where it previously seldom occurred.

That the decrease in malaria in the Klang district, which was the subject of special report to Government, has steadily continued, is well shown by the following figures.

Cases of Malaria with Number of Deaths from that Disease at District Hospital, Klang, during the Last Four Years.

Year.	Cases treated.	Deaths.	
1900	477	31	
1901	820	70	
1902	417	32	Sanitary work carried out at Klang and Port Swettenham.
1903	230	19	

The anti-malarial campaign which was carried out with such success at Klang and Port Swettenham in 1902 has been continued during the past year; the work taken in hand being more especially permanent

drainage. A large tract of mangrove swamp at Port Swettenham has now been converted into well-drained and flourishing pasture.

Beri-beri.

The number of cases of this disease treated during the year was 1,912, with 351 deaths, as against 2,673 with 325 deaths in the previous year, the percentage of deaths being 18.3 and 12·15 respectively. This marked difference is mainly due to the comparative absence of beri-beri from the Pudoh Gaol during the past year.

Deducting the numbers treated in the Pudoh Gaol the figures are as follows:—

Year.	Total cases.	Deaths.	Percentage of deaths.
1902	1,772	308	17·4
1903	1,867	349	18·9

Thus, excluding the returns from the Pudoh Gaol, there has been a slight increase of beri-beri with a corresponding increase in death-rate.

This was most marked at the District Hospital, Kuala Lumpur, where 901 cases were treated, with 192 deaths, as against 839 with 158 deaths in the previous year.

As in former years, the difference between the returns relating to beri-beri in purely mining districts as compared to those in mainly agricultural districts is well marked:—

	Total treated.	Deaths.	Percentage of deaths.	
Kajang	175	11	6·28	agricultural.
Klang	31	3	9·67	,,
Kuala Kubu	164	66	40·45	mining.
Sungei Besi	71	13	18·31	,,

The death-rate from beri-beri at Kuala Kubu is extraordinarily high, and is being carefully enquired into.

The comparative absence of beri-beri from the agricultural districts is, in my opinion, mainly due to the scattered nature of the population. This favours the theory that beri-beri is an infective disease, the coolies when crowded together in mining kongsis being much more liable to be attacked than the gardeners and agriculturists, who mostly live in small separate huts.

Pulmonary Disease.

The number of cases treated for diseases of the lungs was 811 with 266 deaths, as against 850 cases with 241 deaths in the year 1902. Of the 266 deaths 177 were due to phthisis.

The fact that the number of deaths due to disease of the lungs exceeded that caused by malarial fevers or dysentery shows how necessary it is that the question of overcrowding in the towns, with the accompanying evils of bad ventilation and deficient light in the houses, should receive the careful attention of Government.

The difficulty is likely to become a very serious one, and the subject of phthisis was discussed at the Medical Congress held in 1902, when certain recommendations were made to Government with a view to checking the spread of this disease.

Venereal Disease.

The number of cases of venereal disease treated in hospital was 847 with 16 deaths, as against 844 with seven deaths in 1902.

Zymotic Disease.

Plague.—A small outbreak of plague occurred at Kuala Kubu, causing about 15 deaths. Of these cases three were treated at the District Hospital, Kuala Kubu, and two at the District Hospital, Kuala Lumpur. All the cases proved fatal.

Small-pox.—One case of small-pox was removed from a ship calling at Port Swettenham and was treated at the Quarantine Station.

Cholera.—A few cases of cholera occurred at Rawang in the mining kongsi; none of the cases were admitted to hospital.

Vaccination.

Most districts in the State were visited by the vaccinator during the year.

The number of persons vaccinated during the last three years were as follows:—

Year.	Number vaccinated.	Successful.	Failed.	Not seen.	Per-centage.
1901	2,297	2,074	24	199	89·89
1902	2,774	2,748	20	6	99·09
1903	3,236	3,176	18	42	98·14

Saigon buffalo lymph was used in all cases and was satisfactory in every way.

Infants of all nationalities are readily brought to the various centres appointed, and the advantages of vaccination are more thoroughly appreciated in Selangor than in England. The necessity for re-vaccination is, however, not understood, and although the infant population is now well protected, it is quite possible that large numbers of adults might be attacked under circumstances favouring the spread of the disease. Although not willing to be revaccinated under ordinary circumstances, I find that no objection to revaccination is raised by adults of all nationalities should a few cases of small-pox occur in their immediate neighbourhood.

Out-patients.

The number of persons applying for treatment as out-patients at the various hospitals and infirmaries was 36,174, as against 38,476 in 1902.

The District Hospital, Kuala Lumpur.

This hospital was throughout the year under the care of District Surgeon Dr. A. J. McClosky, who reports as follows:—

"*Admissions.* — Four thousand and forty-eight patients were admitted during the year, which, with 282 remaining from the previous year, gives a total treated of 4,330. The admissions exceeded those of last year by 16, while the total treated was less by 48.

"The following table shows the total treated for each of the last five years:—

Year.	Total treated.	Year.	Total treated.
1899	3,584	1902	4,378
1900	3,033	1903	4,330
1901	5,086		

"The following diseases caused the largest number of admissions, viz.: Beri-beri 801, ulcers 575, rheumatism 436, malarial fever 245, dysentery 243, diarrhœa 156, phthisis 142.

"The condition of many of those admitted was, as in previous years, very unsatisfactory, many cases being hopeless from the very beginning.

"The daily average number of sick was 288·62, a considerably lower figure than last year, which was 336·31.

"*Mortality.*—Seven hundred and twenty deaths occurred during the year, representing a mortality of 16·62 per cent., against 736 deaths and a mortality of 16·77 per cent. last year; 97 deaths occurred within 48 hours of admission.

"The following diseases caused the largest number of deaths :—

	1903		1902	
	No. of Deaths	Per-centage	No. of Deaths	Per-centage
Beri-beri	192	21·30	158	18·84
Dysentery	109	44·85	129	51·08
Phthisis	100	66·22	103	66·02
Diarrhœa	77	48·42	142	46·25
Cirrhosis of Liver	32	60·37	21	63·62

"*Special Diseases: Beri-beri.*—The admissions from this disease exceed those of last year by 40, and the death-rate is also slightly higher.

"The following table shows the admissions and death-rate for the last five years :—

Year.	Admissions.	Death-rate.
1899	720 ...	21·11 per cent.
1900	836 ...	20·91 ,,
1901	599 ...	21·55 ,,
1902	761 ...	18·84 ,,
1903	801 ...	21·30 ,,

"Forty-three patients were transferred to Jeram during the year.

"*Dysentery.*—The return shows 243 cases treated, 109 deaths and a death-rate of 44·85 per cent. Three of the deaths were complicated with abscess of liver, in two of which there were multiple abscesses. In all three amœbæ were demonstrated.

"*Diarrhœa.*—One hundred and fifty-nine cases were treated with 77 deaths and a death-rate of 48·42 per cent. The number of cases treated is considerably less than last year, when 307 cases were treated.

"*Malarial Fever.*—Two hundred and fifty-three cases were treated; this is an excess of 74 over last year. The types were :—

	1903.	1902.
Malignant	136 ...	81
Benign quartan	79 ...	55
Benign tertian	26 ...	43
Mixed types	12 ...	—
Total ...	253 ...	179

"The mixed types were :—

Malignant and benign tertian	6
Malignant and benign quartan	1
Benign tertian and quartan	5
Total ...	12

"Sixteen deaths were directly attributed to this disease, giving a death-rate of 6·32 per cent. All the deaths were from the malignant type. The districts from which most of the cases came were Kuala Lumpur (chiefly Batu Road and Java Street) 55, Gombak 45, Ampang 28, Kepong 12, Panthai 10.

"*Phthisis.*—The return shows 151 cases treated, with 100 deaths, but this disease complicated five other diseases, and was their immediate cause of death. The percentage of deaths, therefore, is 67·3. Several of the cases involved the bowel as well as the lungs.

"*Enteric Fever.*—Ten cases were treated, with eight deaths. Two of the patients died within 48 hours. Most of the cases proved fatal from perforation and peritonitis. One case was convalescent, when he ate some guavas and got a relapse with perforation and peritonitis. This is a form of accident which it is extremely difficult to prevent.

"*Plague.*—Two cases were admitted during the year. One was of the bubonic type and was transferred to the infectious ward, where he subsequently died. This case was treated with 5 grs. carbolic acid thrice daily. The other case was admitted with very high temperature and died the next day. No clinical signs were found to account for the high temperature, and the blood examination for malaria was negative. At the autopsy the only morbid appearance found was a number of small pin-point abscesses scattered throughout the spleen. Culture was made from the spleen, and the *Bacillus pestis* demonstrated. This was evidently the septicæmic type; there were no buboes.

"*Post-mortem Examinations.*—Two hundred and eight were performed at the District Hospital and 138 at the Institute for Medical Research by the Director and his staff.

"*Out-door Patients.*—Three thousand and twenty-seven were treated, consisting of 2,329 new cases and 698 repetitions. This is a total increase of 478 and an increase of 558 of new cases as compared with last year.

"*Vagrant Ward.*—Thirty-five cases were treated in this ward, with nine deaths and a death-rate of 25·71 per cent.

"I cannot conclude this report without expressing my thanks to the Director, Institute for Medical Research, and his staff for their valuable assistance in making *post-mortem*, bacteriological and blood examinations, &c."

The Leper Asylum.

Dr. A. J. McClosky, District Surgeon, in charge of this institution, reports as follows :—

"One hundred and twelve lepers were admitted, against 107 last year, and the total treated was 240, against 232 last year.

"Of the admissions, six were Tamils, one Malay and the rest Chinese. Forty-three absconded and 70 died.

"The mortality was 29·16 per cent. Several of the old inmates died during the year.

"The following table shows the comparative figures for the last three years :—

	Admitted.	Total treated.	Absconded.	Died.	Mortality.
1901	95	230	70	34	14·78 per cent.
1902	107	232	49	54	23·27 ,,
1903	112	240	43	70	29·16 ,,

"The increase in the admissions is not a standard to go by in judging of the prevalence of the disease, as several were readmissions of absconded lepers. This year I propose to note the new admissions and re-admissions.

"Discipline was well maintained during the year.

"The swamps to the south and east of the hospital were filled in. Quarters for four gardeners were erected outside the hospital compound."

The Pudoh Gaol.

The infirmary at the Pudoh Gaol was throughout the year under the care of the State Surgeon.

The average number of prisoners in the gaol was 448. I am glad to be able to report that throughout the year the prisoners enjoyed excellent health.

The total number of prisoners treated in the infirmary was 295, with a death-rate of 2·37 per cent., as against 1,169 with a death-rate of 2·56 in the previous year.

I attribute the good health of the prisoners partly to the improvement in the ventilation of the gaol, and partly to the arrangement by which the greater number of the prisoners were employed at extramural work.

Beri-beri.—For the first time for eight years the prisoners have been practically free from beri-beri, Fifteen cases remained under treatment on January 1st, and during that month 22 cases were admitted. Of these 14 were relapses and eight fresh cases: of the eight fresh cases only three had no previous history of beri-beri.

During the rest of the year only nine cases were admitted, and of these only two had no previous history of beri-beri and probably originated in the gaol.

Two prisoners died from beri-beri during the year. The following table gives the number of cases of beri-beri admitted to the infirmary each month during the years 1902 and 1903.

Month.	1902.	1903.	
January ...	68	22	
February ...	44	*nil*	
March ...	63	,,	
April	80	,,	
May	91	,,	
June	83	,,	
July	67	,,	
August ...	75	,,	
September ...	131	1	
October ...	9	2	(one awaiting trial)
November ...	35	5	(four relapses, one awaiting trial)
December ...	55	1	(a very doubtful case).

The want of regular hard labour, such as stone-breaking, was severely felt throughout the year.

The General Hospital, Kuala Lumpur.

This hospital has at different periods during the year been under the care of District Surgeons Dr. Gerrard, Dr. Davies, and recently of Dr. Fletcher, who reports as follows upon the year's work:—

"The number of patients treated during the year 1903 was slightly larger than for the year 1902, the numbers being—

1902 ... 2,170 | 1903 ... 2,244

"The number of deaths was small (106), the percentage of deaths to the total number of patients treated being 4·72 for both sexes taken together, and only 2·99 for men. Twenty-five patients were admitted to the European Ward during the year as against 35 in 1902.

"The old ward was vacated at the end of the year, and the new European hospital has now been opened.

"The number of patients treated in the Female Ward was 339, with 49 deaths. The percentage of deaths in this ward was therefore 14·45, whereas for the rest of the hospital it was only 2·99.

"Most of the patients admitted to this ward are either paupers, estate coolies, or prostitutes, and are generally so ill before they seek admission that little can be done for them.

"Dysentery (including diarrhœa) and phthisis were responsible for 19 of the 49 deaths.

"At present one-third of the women in hospital are suffering from phthisis in an advanced stage.

"An extension of this ward is to be built during the current year for women of the better class. This should prove of great service, as there is at present no provision for the hospital treatment of women whose husbands are in the position of junior Government clerks, &c., and do not care for them to go into a ward where a considerale proportion of the patients are prostitutes.

"*Malay States Guides.*—During the year 1903, 235 Malay States Guides were treated in hospital, with no deaths. In 1902, 220 cases were treated, with one death. These figures speak well for the health of the two companies quartered in Kuala Lumpur. The principal diseases for which they were admitted to hospital were malaria (60) and injuries (45).

"*Police.*—The admissions into the Police Ward were 567, with two deaths (from dysentery and diarrhœa). In 1902, there were 587 admissions, with three deaths. The number of admissions is large, but that the diseases from which these patients suffered were generally not of a serious nature is shown by the small death-rate of 0·35 per cent. One hundred and thirty-five of the admissions were for malaria, 44 for constipation and 16 for dyspepsia."

The New European Hospital.

This institution, with nurses' quarters and house for surgeon, was completed during the year. The hospital is an excellent one and is well equipped with every convenience for the comfort of patients. No expense has been spared in furnishing the wards and operating theatre in accordance with the most recent improvements. The hospital is, however, some two miles from the town, and being on a steep hill is difficult of approach. I fear that little use will be made of this institution by the public until it is in charge of a resident surgeon, and until some kind of suitable ambulance is provided by Government to convey patients to it.

The Lunatic Asylum.

The number of lunatics treated in asylum during the year was 180. There were 122 admissions; 75 were discharged cured or to care of friends, and 52 died. The death-rate was 28·88 per cent., as against 21 per cent. in 1902. Of the 52 deaths, 31 were due to dysentery and 10 to beri-beri.

There is no separate infirmary in the asylum for the accommodation of sick lunatics, who have to be treated in a long, low, ill-ventilated room, the ground floor of one of the blocks formerly used as prison cells, the association ward for healthy lunatics being on the upper floor.

As mentioned in my report for 1902, I am of opinion that the present lunatic asylum is in no way suitable for the intelligent treatment of persons of unsound mind. Criminals, cases of idiotcy and maniacs have to be kept together in one room. The wards are low, dark and badly ventilated, and there is no separate accommodation for women or facility for employing or amusing the patients.

Coast Hospitals.

The District Hospitals at Klang, Jugra and Kuala Selangor and the Beri-beri Hospital at Jeram have throughout the year been under the care of District Surgeon Dr. Watson, who reports as follows on the work done at each hospital :—

"*District Hospital, Klang.* — There has been a decrease in the number of patients admitted to hospital, and an increase in those treated as out-patients.

Year	In-door			Out-door	Out and In-door
	Total treated	Deaths	Mortality	Total treated	Percentage of malaria
1901 ..	1822	232	12·73	2789	38·8
1902 ..	1406	153	10·88	2389	20·48
1903 ..	1218	124	10·18	2688	12·11

"The mortality, after deducting deaths of 18 persons dying within 48 hours of admission, was 8·7 per cent. against 7·46 per cent. in 1902, and 8·61 per cent. in 1901.

"*Prevalent Diseases.*—The following table shows the more prevalent diseases :—

Disease.	No. treated.	No. of deaths.	Mortality.
Dysentery and diarrhœa	118	39	33·00 per cent.
Malaria	230	19	8·26 ,,
Pneumonia	35	13	34·28 ,,
Phthisis	17	7	41·17 ,,
Ulcer	193	1	0·05 ,,
Beri-beri	38	3	8·67 ,,

"Bowel complaints as usual head the list of deaths, even although there has been a decrease from 56 in 1902 to 39 in 1903.

"It is extremely satisfactory to note that along with the great decrease in the amount of malaria the number of cases of other diseases treated has only increased very slightly, the population having rapidly increased.

Year	In-door admissions		Out-door total treated	
	Fever	Other diseases	Fever	Other diseases
1901 ..	807	962	965	1824
1902 ..	403	953	364	2025
1903 ..	219	925	245	2443

"In the towns of Klang and Port Swettenham malaria has been reduced to an almost negligible factor, a saving of at least 800 lives having been effected in the last two years.

"*Infectious Diseases.*—Two cases of small-pox were treated, one from a steamer and one on an estate, but in neither instance did any spread of infection occur.

There has been no cholera. Two cases of typhoid fever were admitted towards the end of the year.

"*District Hospital, Jugra.*—The number of patients treated is shown in the following table :—

Year	In-door			Out-door	In-door and Out-door	
	Total Treated	Deaths	Mortality	Total Treated	Number	Percentage o Malaria
1901 ..	434	46	10·46	1204	915	55·8
1902 ..	267	21	7·63	567	279	33·4
1903 ..	209	12	5·82	1066	328	26·09

"The improvement in the health of Jugra begun in 1902 is most encouraging. During 1902 a little draining was done, and this year several most obnoxious pools in the vicinity of the hospital and the District Officer's and boatmen's quarters were drained, while a considerable amount of jungle was cleared away. During the two years quinine has been regularly distributed to school children and coolies.

"The Public Works Department lines at the 17¼ mile have been removed to a more healthy site on the Klanang road.

"To these measures I think we must attribute the improved health of Jugra; and, judging from the ease with which malaria has been dealt with in Klang and Port Swettenham, there is every encouragement to proceed with the work at Jugra.

"*District Hospital, Kuala Selangor.*—The work done during the year is shown in the following table :—

Year	In-door		Out-door
	Total Treated	Mortality	Total Treated
1901	221	3·16	1317
1902	158	8·22	1770
1903	168	4·16	1314

"The large number of out-door patients compared with number of in-door is due to the district being a Malay one. Although the Malays, as shown by the number who attend as out-patients, have faith in European medicines, it is a matter for regret that the conditions within the hospital have not yet been made such as to attract them as in-patients. They are thereby unable to avail themselves of the most valuable part of European treatment.

Medical Report on the State of Selangor for the Year 1903.

By E. O. A. TRAVERS.

State Surgeon.

"*Beri-beri Hospital, Jeram.*—This is the third complete year of this hospital's existence, and, as I pointed out, it acts as a district hospital for Jeram as well as a beri-beri hospital. The room taken up by the other diseases should not be grudged, as it keeps the dresser in more active touch with his work than if he had simply to attend convalescent beri-beri cases. The number treated was as follows :—

	1901.	1902.	1903.
Beri-beri	138	112	114
Malaria	27	31	29
Other diseases	46	49	52
Total death-rate	15·11	10·41	9·23
Beri-beri total death-rate	21·69	12·50	10·52

"It is satisfactory to note the still further decrease in the death-rate of the beri-beri patients. It will further decrease, I hope, as the compound is better drained.

"The number of beri-beri who contracted malaria was less than it hitherto has been, and I had hoped that by locking up the patients at night this number would have been still further reduced. Unfortunately, towards the end of the year, a large part of the mosquito-proof gauze was damaged by the wind.

"The compound has been still further improved, and the drainage would now be quite satisfactory could the outlet drain be kept open. This, however, appears to be impossible, and a new scheme for drainage is under consideration.

"Again I have pleasure in recording an improvement in the health of this district as a whole, the percentage of malaria treated at the hospitals having fallen from 23 per cent. in 1902 to 14·1 per cent. in 1903. This great improvement has been brought about by the drainage of the inhabited parts of the district, of which not the least important work was the Jeram drainage scheme.

"A very large area has been drained and shares in the improvement, which is extremely satisfactory and encouraging."

Ulu Selangor Hospitals.

The district hospitals at Kuala Kubu, Rawang and Serendah have throughout the year been under the care of District Surgeon Dr. Delmege, who reports as follows on the work done during the year :—

"The total number of cases treated was as follows :—

	In-patients.	Death-rate.	Out-patients.
District Hospital, Kuala Kubu	1,927	20·4	6,069
,, ,, Serendah ...	1,080	11·6	3,831
,, ,, Rawang ...	930	10·09	2,226
Dispensary			4,865

"There has been an increase in mortality at Kuala Kubu and Serandah, and a decrease at Rawang."

The very high death-rate among patients at the Kuala Kubu Hospital calls for special mention. It will be seen that it is almost double that for the other two hospitals in the district. The diseases causing the largest number of deaths were :—

	Cases.	Death-rate.
Diarrhœa ...	293	... 42·66 per cent.
Dysentery ...	89	... 65·16 ,,
Beri-beri ...	164	... 40·45 ,,

The death-rate among cases of beri-beri treated in the other two hospitals in the same district was 9·25 per cent. at Serendah and 7·52 per cent. at Rawang.

It is difficult to account for the extraordinary difference in the mortality at these three hospitals. The patients are drawn from a mining population in each case, and the hospital accommodation and equipment at Kuala Kubu is superior to that at Serendah and Rawang.

During the present year every effort will be made to reduce the death-rate, and it is hoped that an appeal to the mining community will result in the admission of the miners at an early stage of disease, when there will be a reasonable hope of their recovery.

District Hospital, Kajang.

This hospital has throughout the year been under the care of Apothecary Ngai Leung. The work done at this hospital was as follows :—

Year.	Total treated.	Deaths.	Death-rate.
1902 ...	1,223 ...	87 ...	7·11 per cent.
1903 ...	1,105 ...	90 ...	8·14 ,,

One hundred and seventy-five cases of beri-beri were treated, with 11 deaths, giving a percentage of 6·28.

Veterinary Department.

Mr. T. A. Ford, Veterinary Surgeon, reports as follows upon the work done during the year :—

"The following outbreaks of epidemic disease occurred during the year :—

"*Rinderpest.* — At eighth mile Cheras road and twelfth mile Langat road seven bullocks and seven buffaloes died ; I could not trace the origin of this outbreak. The disease did not spread to any extent, only the immediate in-contact animals being attacked. The outbreak was generally of a subacute type, most of the animals living for four or five days, and in some cases longer. Strict isolation of all animals, with closing of the roads at seventh and tenth mile Cheras and fourteenth mile Ulu Langat roads from August 29th for five weeks was found sufficient to prevent any spread of the epidemic.

"At the cattle quarantine station, Port Swettenham, an outbreak occurred on November 11th, when a buffalo recently landed from Penang died suddenly, and was found on *post-mortem* examination to have died of rinderpest.

"The disease spread very rapidly among the cargo of thirty buffaloes and from them to the bullocks in other sheds, and was the cause of twenty-seven deaths. Eight buffaloes were shot in the early part of the epidemic, with the hope of stamping out the outbreak. On November 22nd the disease had spread amongst the bullocks, and the infection was so

general I deemed it useless to destroy any more sick beasts, with the result that ten bullocks and three buffaloes recovered, and were released on December 20th.

"A number of *post-mortem* examinations were made in conjunction with Dr. Daniels, Director, I.M.R.

"On the question of the treatment of rinderpest, I may mention that acute cases succumb so rapidly there is no time to do anything; but in the subacute cases, after consultation with Dr. Daniels, who suggested magnesia sulphate (Epsom salts), I decided to take two cases which were passing watery stools, mixed with a good deal of blood, and sloughing mucous membrane.

"The doses given were about 2 ozs. in half a pint of water four times a day. The effect was to stop the straining and bleeding, and I think the animals looked brighter and more inclined for food; some other cases in which this drug was given without my knowledge, until they were released, also did well. This is not a specific, but appeared to guide the disease through one of its stages, by rendering the stools more watery and capable of being passed with less straining.

"*Foot-and-Mouth Disease.*—With the exception of the months of June, July and December, this disease has prevailed during the whole year, small, more or less isolated, outbreaks occurring all over the State. The total number of animals attacked was 354, and the most in any one month was 124 in September, Compared with 1902, these numbers are very small. and the improvement is, I think, due to the greater vigilance shown in isolating animals and the much drier weather.

"*Rabies.*—Four cases of this disease were met with during the year, in June and July; one a case of furious rabies which bit two people, another was a case of the dumb form of the disease. The other two dogs both showed obscure symptoms of being ill, but nothing in any way diagnostic. Rabbits inoculated with brain matter from these four cases all died, after a longer or shorter period of incubation, of paralytic rabies, the usual form for this disease to take in the rabbit. I would also remark that, so far as I am aware, although several dogs were bitten, in no case had rabies developed in any of the bitten animals, and I have carefully watched three dogs, undoubtedly bitten by subsequently proved to be rabid animals, which up to the time of writing have remained perfectly healthy.

"*Surra.*—One case of this disease was found in an Australian horse belonging to H.H. the Sultan of Selangor, and the parasite *(Trypanosoma wansi)* demonstrated to Dr. Daniels, who saw the case with me. Rats and guinea-pigs inoculated at the Institute of Medical Research with the blood from this horse died, and the parasites were found in abundance in the blood of the guinea-pigs. I have not heard that this disease has been met with in the F.M.S. before, and made it the subject of a special report to Government.

"*Prosecutions.*—During 1903 the following prosecutions were conducted: For adulterating pork with water, four at Kuala Kubu; fines from 50 dollars to 100 dollars were imposed. For insanitary sheds, 13; fines from 8 dollars to 50 dollars. For removing diseased and in-contact animals, 5; fines from 50 dollars to 200 dollars. For not reporting contagious diseases, 6; fines from 15 dollars to 50 dollars. For allowing cattle to stray contrary to *Gazette* notification, 4; fines from 10 dollars to 25 dollars. For cruelty to a bullock by burning his eyelids, 1; fined 50 dollars. For not registering as a cowkeeper, 1; fined 50 dollars.

"*Milk Licences.*—Sixty-seven licences were certified for during 1903, representing buffalo cows 113, calves 71, cows 266, calves 252, owned in Kuala Lumpur for milking purposes, a total of 702 animals. All the cowsheds are floored with cement or good bricks before a certificate of fitness to keep the animals is granted, and I find I now have little difficulty in getting the owners to keep their pens clean and sanitary."

Examination of Petroleum at Port Swettenham.

The testing of petroleum was carried out by the Deputy Health Officer at Port Swettenham under the superintendence of Dr. Watson.

The total petroleum imported was 1,102,392 gallons. No petroleum was rejected as unsafe.

Six thousand five hundred and fifty-two gallons of gasoline were also imported.

The number of samples of petroleum tested was 41, and the revenue collected was $565.

The following returns are attached:—

(*a*) Return of patients treated in all hospitals during the year 1903;

(*b*) Return of diseases more commonly treated with percentage of deaths during 1902 and 1903;

(*c*) Number of beri-beri cases treated in State hospitals from 1883 to 1903;

(*d*) Return of sick convicts treated in the gaol from 1883 to 1903;

(*e*) Vaccination return for the State for the year 1903;

(*f*) Return of small-pox treated in the State during the year 1903;

(*g*) Comparative return of out-door patients treated from 1894 to 1903;

(*h*) Number of police admitted into the General Hospital from 1901 to 1903.

No. 6.—FEDERATED MALAY STATES.

RETURN OF DISEASES AND DEATHS IN 1903 AT ALL HOSPITALS IN SELANGOR.

No. 7.—FIJI.

MEDICAL REPORT FOR 1903.

By B. GLANVILLE CORNEY, Chief Medical Officer, Fiji.

Population.

(1) The estimated population of the colony at the end of the year amounted to 121,074 persons, and was made up of the following classes in the proportion shown :—

	Males	Females	Total
Europeans and other Whites ..	1,580	1,011	2,591
Aboriginal Fijians	48,522	42,381	90,903
East Indian Immigrants (including their children born in Fiji)	14,233	7,268	21,501
Melanesian and Malayo-Polynesian Immigrants	1,617	350	1,967
Rotumans	1,034	1,041	2,075
Half-castes and other degrees..	800	777	1,577
All others..	250	210	460
Total	68,036	53,038	121,074

These figures represent a decrease of 851 from the foregoing year's estimated population, caused mainly by an increased mortality among the aboriginal Fijians, the natives having diminished during the twelve months by 2,481.

Births and Deaths.

(2) The total births registered numbered 4,226, or six less than in the previous year. The total deaths amounted to 6,551, as against 4,306 during 1902, the abnormal mortality of 2,245 (or at the rate of over 52 per cent.), being partly caused by an epidemic of measles. Arrivals and departures from the Colony were not enumerated.

The birth-rate calculated on the *mean* total population for the year was 34·78 per mille, and the death-rate on the same basis was 53·91 per mille. The former figure was ·75 below, and the latter 18·60 per mille above, the corresponding results in the previous year. These figures are calculated on the estimated mean population, all races and classes, as obtained from the Registrar-General's returns. Details of the population of the Island of Rotuma, a dependency of the colony, are appended.

(3) Some further particulars regarding the births, deaths, and marriages which took place among the various racial denominations in the colony are afforded in the following tabular statement :—

Races or Nationalities	Births	Deaths	Marriages
Europeans	93	50	23
Fijians	3,244	5,727	1,027
Indians	730	570	349
Polynesians	8	54	9
Rotumans	108	110	31
Half-castes	37	31	16
Others	6	11	4
Total	4,226	6,551	1,459

Nearly all these figures differ rather materially from the corresponding ones for 1902, except the total number of births. The increased mortality has been alluded to in paragraph (2), and there is a falling off in marriages to record, which may perhaps be partly accounted for by the same cause.

(4) The table of vital statistics appended (Return A) relating to the various racial populations in the colony is prepared in accordance with the suggestions circulated in the Model Medical Report Form, and is intended to express the information it contains in a form convenient for comparison with those from other Crown colonies.

Measles Epidemic.

(5) The one prominent occurrence during 1903 was an epidemic of measles, the first cases of which occurred in a straggling way in the vicinity of Suva, and appeared to be indirectly traceable to a convalescent European who arrived from New Zealand.

A special report on this outbreak by Dr. G. W. A. Lynch, the Senior Medical Officer, who was acting for the Chief Medical Officer (on leave) during the whole time of its continuance, is appended. In it is shown that nearly half the aboriginal population was attacked to the number of 44,385 cases, and that the deaths among them from this cause amounted to 1,825, which is at the rate of 41·11 per mille attacked, whereas among the 1,113 cases of measles which occurred in all other races in the colony during the same period the deaths were only 7, or at the rate of 6·28 per mille of cases.

The general epidemic of measles which occurred in Fiji in 1875, attacking almost every native, when their total population was estimated to be 150,000, was accountable for some 40,000 deaths, a ratio of more than one in four.

The greatly lessened mortality from the epidemic of 1903 is attributable to (1) immunity of half the population through previous attack ; and (2) the effect of this immunity of half the population, whose services in attending on the sick, restraining them, and providing for them, were thereby secured ; (3) special teaching and cautions given to the people in every village by means of printed circulars regarding the nature and treatment of measles ; and (4) general advance in instruction and civilisation of the people during the thirty years.

The mortality, which was nevertheless higher than is usual among Europeans and other civilised peoples, is ascribed chiefly to enteritis and dysentery, occurring as sequelæ, and to the "obstinacy and folly, not ignorance," of the adult patients in disregarding the cautions and instructions circulated among them, and in yielding to the impulses of the moment, such as appetite for food, or desire to bathe, without regard to consequences.

No death from measles occurred in any European patient.

Enteric Fever.

(6) At Ba and Rewa, both populous sugar-mill centres, series of cases of enteric fever took place, with some fatalities, and assumed more grave dimensions than heretofore recorded in the colony.

Hospital Statistics.

(7) The subjoined table represents the monthly numerical fluctuations in the admissions to the Colonial Hospital :—

	Jan.	Feb.	Mar.	Apl.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Whole Year
Europeans ..	18	6	13	14	7	9	12	8	13	5	12	15	132
Fijians ..	43	47	231	143	45	42	29	45	44	40	54	43	806
Indians ..	50	62	40	39	38	35	73	82	43	33	21	44	560
Melanesians ..	3	7	9	17	4	2	6	2	2	6	3	13	74
All others ..	1	10	5	7	3	3	1	2	4	5	2	15	58
Monthly Totals	115	132	298	220	97	91	121	139	106	89	92	180	1630
Quarterly		545			408			366			311		

(8) The preponderance of admissions in the months of March and April was caused by an epidemic of measles among the native Fijian populations, Indian coolies being immune through previous attacks in India or during the voyage to the colony; and Europeans not resorting to the hospital for this ailment.

(9) Of the admissions to the Colonial Hospital, cases of general disease numbered 899; and local diseases 715. The former included 358 cases of measles, of whom 295 were native Fijians, 20 Melanesians, 25 Indian immigrants or their children born in Fiji, 12 Europeans, and the remaining 6 miscellaneous South Sea Islanders. Dysentery accounted for 99 admissions, of whom 11 were Europeans, 26 Fijians, 6 Melanesians, 54 Indians, and 2 miscellaneous.

Framboesia.

There were 37 cases of secondary framboesia, 35 of whom were Indians; and 95 of tertiary framboesia, 88 of whom were Fijians. The notable diminution in the cases of the last named is due in part to the establishment of provincial hospitals for Fijians, but is also to some extent probably explainable by the adoption of a slightly different system of classifying them in the returns, owing to a temporary change in the medical staff of the hospital. But the absence of primary and secondary framboesia again illustrates the indifference with which the native race regards this damaging disease, and the unwillingness of the people to place themselves under European treatment for it.

Malaria and other Diseases.

Only one case of malarial fever (a Melanesian) occurred. Only 14 cases of syphilis were admitted; these were all Indian immigrants, 1 primary, 6 secondary, 5 tertiary, and 2 inherited. Of gonorrhœa 19 cases in all were admitted, of whom 18 were Indians. No case of syphilis in any stage in a Fijian was recorded throughout the colony.

Tubercular conditions accounted for 31 admissions; 23 of them were Fijians. The 15 admissions for filariasis were all Fijians; while the 13 of anchylostomiasis, and the 7 of guinea-worm, were all Indians, as well as 14 cases returned as anæmia.

Neoplasms.

(10) Among neoplasms 6 were benign (fibroma and lipoma, all in Indians), and 13 were set down as malignant. The malignant cases were as follows, and this information has been forwarded to the Imperial Cancer Research Laboratories, London :—

Epithelioma of face ...	2 Europeans.
Carcinoma of pylorus ...	1 Fijian, 1 Indian.
,, parotid gland	1 European.
,, mamma ...	1 Indian.
Sarcoma of face	1 Fijian (aged 10 years).
,, tonsil	1 European, 1 Melanesian.
,, orbit	1 Fijian.
,, inferior maxilla	1 half-caste Fijian.
Malignant tumour of kidney	1 half-caste Fijian.
,, ,, pelvis	1 native of Africa.
Total	13

Local Diseases.

(11) Of the 715 cases of local diseases, 44 belonged to the nervous system, 37 to the eye, 10 to the ear, 6 to the nose, 18 to the circulatory system, 170 respiratory, 157 digestive, 17 lymphatic, 12 urinary, 57 generative, 16 locomotory, 109 connective tissue, and 62 skin.

(12) Only 4 cases of general injury were received, but 74 of local injuries.

Operations.

(13) Two hundred and ninety-five surgical operations were performed in the Colonial Hospital at Suva during the year, namely, 8 on tumours, 8 on cysts, 88 evacuations of abscesses by incision and drainage, 5 extractions of foreign bodies, 2 operations on veins, 23 on glands, 1 on a nerve, 60 on the skin and subcutaneous tissues, 3 on bones, 3 on joints, 18 were amputations, 3 operations on the skull, 11 on the jaws, nasal cavities and mouth, 6 on the eye, 7 on the thorax, 16 on the abdomen (including 4 laparatomies), 4 on the rectum and anus, 4 on the bladder and urethra (not counting simple catheterisation), 19 on the male generative organs, and 6 on those of the female. Of these operations, 40 were performed on European patients, 157 on native Fijians, 74 on Indians, 10 on Melanesians, and 14 on persons of other nationality.

Deaths in Hospital.

(14) The number of deaths which took place in the hospital was 65, of which 6 occurred in Europeans, 22 in Fijians, 2 in Melanesians, 30 in Indians, and 5 in other persons.

Of the 15 cases of enteric fever (of whom 8 were Europeans, 1 a Fijian, and 6 Indians) no death took place.

Work in Provincial Hospitals.

(15) It is possible this year for the first time to include in this report some particulars of the work carried on in certain minor hospitals recently established in more or less remote parts of the colony for the special convenience and physical amelioration of the aboriginal Fijian population. This work has

been undertaken in connection with reforms suggested in the report of the Commission appointed in 1893, to enquire into the causes and possible remedies for the rapid decline of the native race which has been, and still is, taking place.

Seven of these provincial hospitals have been provided in Fiji proper, and one in Rotuma, each under the care of a resident European medical officer, assisted by a native practitioner, a native dresser, and staff of servants.

(16) The following table shows the class of diseases met with in the provincial hospitals; but must not be taken to represent the general prevalence of acute illness among the natives, because these disappointing people persistently decline to resort to hospital treatment in just those circumstances when they might expect to derive most benefit from European medical skill and nursing:—

The largest number of admissions was for frambœsia in its tertiary stages; next in order came tinæ imbricata (tokelau ringworm), diseases of the digestive system, skin, and respiratory system. Tubercle accounted for 88 admissions, with only 3 deaths, a figure which also points to the preference shown by the native to die on his ancestral hearth, rather than risk missing the beaten path to a future paradise by permitting his "spirit" to depart from him within the four walls of a white man's hospital; even though it be built on his own soil and for his special patronage, and maintained partly at his own expense.

Of the provincial hospitals that at Bua was only opened in May, that one at Nadroga in July, and that at Rotuma in July also. The absence of a return from the one at Ra is accounted for by the illness, absence on leave, and finally resignation of the medical officer in charge of it, and the subsequent loss

TABLE SHOWING THE NUMBER OF ADMISSIONS TO PROVINCIAL HOSPITALS FOR NATIVE FIJIANS, AND THE NUMBER AND CAUSES OF DEATHS THEREIN DURING 1903; AND THOSE OF ROTUMANS SEPARATELY.

Dec. ..			87·7	73·0	96·5—68·3	82	4·78		E.	1 28/31	
			83·1	71·0	88·7—65·2		6·76		E. to S. E.	2	

Highest corrected reading of barometer ..30·222, on Aug. 7th.
Lowest corrected reading of barometer ..29·529, on Jan. 17th.
Highest temperature in shade .. ..96·5, on Dec. 24th.
Lowest temperature in shade .. ..59·3, on July 15th.
Greatest rainfall in one day .. ..9·18, on March 14th.
Total rainfall during the year .. ..81·09.
Number of days on which rain fell ..207.

Local deviations from those figures depending upon elevation, distance from the sea and aspect, are of course very considerable, more especially as regards rainfall, and the temperature by night.

The year's weather was on the whole more trying for the human population than usual; but correspondingly advantageous for the principal crops—sugar-cane, cocoa-nuts, and bananas.

PLAGUE.

(18) By way of counterbalance to the losses caused by the measles epidemic, the colony continued to enjoy immunity from bubonic plague.

VACCINATION.

(19) Vaccination was conducted, as heretofore, principally by native practitioners working under supervision by the European district medical officers. The total number of persons successfully vaccinated was only 703, this duty having been seriously interrupted by the measles epidemic.

The lymph was procured from New Zealand, and was of good quality; but the delays incidental to its transmission over considerable distances by sea and land after its reception in the colony necessarily interfered with its efficiency in some of the more remote districts. It was no doubt chiefly for this reason that 58 doubtful and 211 unsuccessful results were enumerated.

FILARIASIS.

(20) Besides the report by Dr. Lynch on the epidemic of measles, which is appended, an interesting note on the occurrence of filariæ in Fijian aboriginals will be found forming Appendix II. From this officer's observations conducted on 608 persons, irrespective of clinical symptoms, it appears that one patient in every four admitted to the Colonial Hospital among the natives proper is the subject of filariasis in one form or another; a result which tallies well with observations made in other parts of Polynesia.

But it does not follow from this that one in four Fijians of all ages, classes, and states of health are affected to this large extent.

RETURN "A."

STATISTICS OF POPULATION, 1903.

(FIJI.)

	Europeans and other Whites	Aboriginal Fijians	Rotumans.	Melanesians	East Indians	Mixed and Miscellaneous	Total

No. 8.—THE GAMBIA.

Medical Report for the Year 1903.

By R. M. FORDE.

Senior Medical Officer.

Hospital.

As mentioned in my half-yearly report, sent forward in July last, the extensive and much-needed additions and alterations in connection with the Colonial Hospital were completed in the early part of the year, and the wards of the main building were again ready for the reception of patients by the middle of April.

The female bungalow was not finished until June, the old wooden bungalow being utilised in the meantime.

The new bungalow is a very solid stone structure with an iron roof, and though this roof looks low from the outside, it is nevertheless a cool and well-ventilated building, being amply provided with doors and windows, and the heat of the mid-day sun being screened off by a wide verandah.

The general hospital accommodation is now in a very satisfactory state; the wards are spacious, well lighted and well ventilated. Each has its own separate bathroom and w.c., the latter quite apart from the ward. Just lately the European ward has been fitted with mosquito-proof wire-gauze frames to the windows and doors, and it is intended to extend this to all the wards. From experience I am able to report that this gauze in no way affects the ventilation, and the ward keeps cool and free from stuffiness; at the same time, there is an entire absence of mosquitoes, flies, and other flying insects.

The old female bungalow has had, for some months, to be used for the treatment of incurable cases, and it should, in my opinion, be added to the hospital as a permanent ward for the reception of such cases.

Water Supply.

With reference to the water supply of the hospital, a new underground 10,000-gallon tank has been added at the back of the new female bungalow; this, with the iron one of similar capacity, gives an ample supply of wholesome drinking water for the European and native staffs as well as the patients, and is an important addition to the water supply in general.

Changes in the Staff, &c.

A third medical officer was added to the staff during the year, and Dr. J. C. Franklin was appointed, and arrived in the colony on April 9th.

Dr. Chichester went on leave on April 26th, and returned on October 10th.

Dr. F. A. Baldwin returned to headquarters from the Protectorate in April, and was attached for duty to the hospital; he proceeded on leave on September 23rd.

Dr. Franklin was on duty with the West African Frontier Force at Sallikeni from April to July. He was also on duty as Commissioner and medical officer at McCarthy Island from August to December, when he returned to Bathurst to relieve Dr. C. R. Chichester, who was about to proceed to Southern Nigeria.

Of the native members of the staff, Mr. T. B. Wright's appointment as steward, storekeeper, and clerk was terminated on September 30th, and Mr. C. Shaw appointed in his place.

Mr. J. Bright, senior native nurse, was dismissed on September 19th, and Mr. J. G. McCauley appointed to the vacancy.

An additional native male nurse was added to the staff, as it was found impossible to do the work satisfactorily with two.

Expenditure and Receipts.

Receipts—Paying patients	£38	1	3
Sale of medicines	41	6	1
Total	£79	7	4
Expenditure—Salaries and allowances	£2,236	6	9
Maintenance of sick, medicines, &c. ..	819	13	3
Total	£3,056	0	0

Statistics.

As shown in the following tables, there was a decided increase in the number of patients treated at the Colonial Hospital during the year, more marked in the out-patient department, where the number of attendances was nearly double that of previous years.

TABLE A.

Patients in Hospital.

	Remaining in Hospital Dec. 31, 1902	Admitted during the year	Died	Remaining in hospital Dec. 31, 1903	Remarks
Europeans ..	Nil	15	2	1	One black-water fever, one bilious remittent with old age. Both recent arrivals from Senegal.
Natives ..	6	440	31	5	
Civil Police	3	48	2	—	
W.A.F.F ..	1	78	2	2	
Total ..	10	581	37	8	

TABLE B.

Results of Treatment, &c.

	Male	Female	
Patients remaining in Hospital Jan. 1, 1903	9	1	10
Patients admitted during the year 1903 ..	443	128	571
Total number treated	452	129	581
Cured	348	100	448
Relieved	54	19	73
Not relieved	11	4	15
Died	31	6	37
Remaining in Hospital December 1, 1903	8	Nil	8
Total number treated	452	129	581
Average stay in days of patients discharged	20	7	
Average stay in days of patients died ..	18	4	

The deaths were due to the following diseases:—

Diseases	No.	Diseases	No.
Apoplexy	2	Meningitis	2
Abdominal tuberculosis ..	1	Nephritis	2
Beri-beri	3	Pneumonia	5
Broncho-pneumonia ..	3	Pyæmia	1
Bilious remittent fever ..	2	Sleeping sickness ..	4
Blackwater fever ..	1	Tetanus	1
Diarrhœa	1	Senility	1
Dysentery	3	Tropical fever	1
Gun-shot wound	1	Tubercular meningitis	1
Enteric fever	1	Ulcer of stomach ..	1

Table A shows an increase of 99 in the number of in-patients over the return for the previous year.

The death-rate was higher than usual among the native patients. An outbreak of beri-beri at the gaol, necessitating the removal of some of the prisoners suffering from that disease to the Colonial Hospital; pneumonia due to exposure owing to the flooding of the lower parts of the town during the heavy rains; dysentery and an increased number of cases of sleeping sickness, accounting for half the number of deaths.

TABLE C.

Out-Patients.

	Old Cases	New Cases	Total
Male	2494	2678	5172
Female	1523	1782	3305
Total number of cases	4017	4460	8477

An increase of 4,652 on that for the previous year. The prevailing diseases were the following:—

Ascarides, abscess, bronchitis, injuries, constipation, intermittent fever, conjunctivitis, neuralgia, diarrhœa, ophthalmia, dyspepsia, otorrhœa, dysentery, rheumatism, febricula, stomatitis, gonorrhœa, skin diseases, ulcers.

The total number of patients treated at the hospital during the year, including in-patients and out-patients, was 9,058. Of the rarer diseases met with there were: Sleeping sickness, 4 cases; beri-beri, 3 cases; enteric fever, 1 case; guinea-worm, 1 case; syphilis, 2 cases.

European Officials.

There were twenty-three admissions on the sick list during the year, one of whom was invalided. The diseases were: Biliousness, 3; lumbago, 2; congestion of liver, 1; lymphangitis, 1; diarrhœa, 2; malarial fevers, 6; febricula, 4; malarial cachexia, 1; gastritis, 1; strain of knee, 1; gout, 1. Case of invaliding, malarial cachexia. There was no death.

Native Officials.

There were thirty-one admissions on the sick list during the year. The prevailing diseases were: Auralgia, intermittent fever, bronchitis, intercostal neuralgia, colic, lumbago, diarrhœa, lymphangitis, dyspepsia, spinal sclerosis. There was no death and none invalided.

European Non-Officials.

Of these there were twenty-five treated for various diseases. As follows: Biliousness, 5; lymphangitis, 1; blackwater fever, 1; malarial fevers, 10; cellulitis, 1; sprain of ankle, 1; dyspepsia, 1; stomatitis, 1; febricula, 1; synovitis, 1; fracture of ribs, 1; ulcer, 1.

The resident European population during the year was 105, and among these there were 48 admissions on the sick list, a large number being cases of a trivial nature. The total number of malarial fever cases was 16, with one case of blackwater fever and one of malarial cachexia. One case of remittent fever was an officer from a warship recently arrived from Sierra Leone, where most likely the infection took place, as several other members of the crew also suffered.

The two deaths that occurred among the non-official Europeans were members of the French Catholic Mission, who had only recently arrived in the colony from Senegal, where they lived from fifteen to twenty years. One was aged over 70, and died during a severe attack of bilious remittent fever, the immediate cause of death being cardiac failure. The other died from blackwater fever, having had three previous attacks in Senegal.

TABLE D.

The following table shows the number of cases of illness and invalidings among Europeans during the past five years, and the number resident in the colony for each year:—

	1899	1900	1901	1902	1903
No. of Europeans Resident	80	71	88	98	105
,, ,, Treated..	66	90	89	26	47
,, ,, Died ..	1	9	4	2	2*a*
,, ,, Invalided	1	Nil	3	2	2*a*[1]

(*a*) Blackwater fever, and bilious remittent fever.
(*a*[1]) One for malarial cachexia.
One for iritis.

Infectious Diseases Hospital.

There was no cases of small-pox or other infectious disease during the year.

The Gaol Infirmary.

With the exception of an outbreak of beri-beri in the first half of the year, the general health of the prisoners was fairly good. The average daily strength of prisoners was 19, and the following is the number of cases of illness treated during the year:—

In-patients	24
Out-patients	152
Total treated	176

There were eight deaths from disease and one by execution. The causes of death were: Beri-beri, 3; heart disease, 2; Bright's disease, 2; pernicious anæmia, 1.

The prevailing diseases were the following: Beri-beri, fever, boils, œdema, catarrh, rheumatism, constipation, ringworm.

The sanitary condition and arrangements were fairly satisfactory during the year, the gaol premises and yard being always kept in a clean state, the cells and corridors washed regularly and Izal disinfectant freely used.

The ventilation of all the ground-floor cells was much improved by enlarging the openings in the doors and also the windows, and the area of some of the older cells was increased by knocking two into one.

This improvement in the ventilation and area of the cells, with a thorough cleansing and disinfecting, had, in my opinion, the effect of completely ridding the prison of beri-beri, the introduction of which was traced to three prisoners who were sent in from a town in the Protectorate, where it was afterwards discovered the disease existed for some time.

It is now nearly eight months since the last case occurred, and at present the health of the prisoners is very satisfactory.

Lunatics.

A lunatic asylum is not considered necessary in Bathurst, as all lunatics are at present sent to Sierra Leone, where there are at present three under treatment from this colony.

General Remarks.

The general health of Bathurst was fairly good during 1903, though the death-rate among the native population was higher than that of the previous year, there being 49 more deaths. This rise was not due to any epidemic disease, as the town was quite free from any disease of this nature during the year, and, in my opinion, it can only be explained by the exceptionally heavy rainfall, which, keeping the low parts of the town flooded for considerable periods, caused much disease and discomfort among the poorer classes of the natives, who were for days, on more than one occasion, unable to light fires to cook their food or dry their scanty garments.

The average monthly number of deaths for the five rainy months was 34, that for the seven non-rainy months being 25. In the previous year, with a rainfall of only a little over half the average, the number of deaths for the same periods was 23 and 21 respectively. This goes to show the deleterious effect of a heavy rainfall on the public health of a low-lying tropical town such as Bathurst.

The health of the resident European population was satisfactory, apart from the deaths of two members of the French mission already referred to, which were the only serious cases of illness among Europeans, all the other cases being of a mild type.

The total number of Europeans resident in the colony during the year was 105; of these, 48 were treated for different ailments, only 17 being cases of malarial fever, including one case of blackwater fever. This record, though not quite so good as that for 1902, shows a continuance of the improved health among Europeans noticed in that year, as a result, I now have no doubt, of the anti-mosquito sanitation systematically carried out by the Board of Health.

TABLE E.

The following table shows the total deaths from diseases at all ages and under five years, and the rate of each 1,000 of the population of Bathurst for the past five years:—

Year	Total Deaths	Rate per 1,000	Deaths under 5 years	Rate per 1,000	Remarks
1899	327	37·15	137	15·56	
1900	350	39·77	120	13·75	
1901	340	36·63	137	15·56	
1902	266	30·22	112	12·72	
1903	315	35·79	130	14·77	

I wish to express my satisfaction at the benefits derived by the hospital from the addition of the European nursing sisters to the staff; they are of incalculable assistance to myself and the medical officer in charge of the hospital in the nursing of patients as well as in the general management of the institution. Both Europeans and natives are much more ready to become in-patients than formerly, as they now know they will receive proper care and attention in the hands of trained European nurses, which the natives as well as Europeans thoroughly appreciate.

Sanitation of Bathurst.

The town was kept in a fair sanitary condition during the year. The usual scavenging was carried out regularly by a gang of twenty labourers and two horses and carts under the supervision of an inspector and an assistant inspector of nuisances. The filling up of Half Die Swamp was discontinued owing to the difficulty of procuring material, and also the scarcity of labour; a large portion of that already levelled up is now built over, and several streets are laid out on it. All rubbish, consisting of house refuse and leaves, &c., raked up in the streets is carried to the back of the town, where it is burnt and utilised for the filling in of the swamp and levelling up depressions in the open areas.

The question of the disposal of human excreta is at present receiving the attention of the authorities, and the adoption of a "Horsfall Destructor" for the incineration of all excrementitious matter is under consideration, but I am afraid that the cost of any method would be found too large for the revenue of this colony. Some improvement could, however, be brought about with reference to the disposal of human excreta by enforcing the adoption in private houses and compounds of a fixed form of masonry closet to take the place of the present insanitary arrangement of simply digging a hole and putting a cask or barrel into it, over which a box or seat is placed; this allows free percolation of the contents into the surrounding soil, and consequently contamination of the neighbouring wells.

No. 8.—Gambia. Medical Report for the Year 1903 (*Continued*).

An ordinance amending the Public Health Ordinance is now in force for the prevention of the tethering of cattle in the streets for grazing, and the result is that the streets are now almost quite free from goats and horses, &c., which were not alone dangerous obstructions to persons walking or driving, but also attracted insects and produced in other ways an insanitary condition of the town.

The attempt made about two years ago to cover the public wells has turned out a failure, as the covers were made too heavy and constructed on a wrong plan, the result being that they are removed altogether from the wells, which are left open as before.

From the result of our experience of a French pump fixed to a well in Hagan Street I am able to recommend that all public wells be fitted with this model and permanently covered either with corrugated iron or concrete, on the same lines as those followed lately at Lagos. In the dry season at Bathurst, owing to the prolonged drought, open wells become the chief haunts of mosquitoes and other insects, and are to a large extent responsible for the propagation of the former pests in that season, as there are no pools or stagnant water in the town to act as breeding-places for them.

Anti-Mosquito Sanitation.

This was kept up steadily during the year, a special gang of ten labourers being employed for the work, which consisted in the collection and removal of old tins, broken bottles, &c., to be disposed of by burial in the waste lands adjoining the town, and the levelling up of depressions and useless ditches in the town.

Before the rainy season set in, the levelling up and clearing of the grass drains was taken in hand, and it was found necessary to take on ten extra labourers in order to complete the work before the heavy rains commenced. This made a great improvement in the condition of the streets in which these drains are, and there were no stagnant pools remaining, the excess of rain-water flowing rapidly away. These drains require much attention during the rainy season, as they become choked up after every shower by the loose sand washed down from their sides, and from the rank grass and weeds that so rapidly shoot up in their courses.

It is very necessary that they should be put in thorough repair, a month or two before the rains begin, by being properly levelled, and opened up at all the crossings.

The inspector of nuisances continues his bi-weekly inspection of all gardens, yards, and compounds, and reports to me daily the result. Wells and other water receptacles are examined for mosquito larvæ, and a strict watch kept on them to see that they are always kept covered. The public wells which are in the charge of the Board of Health are not, I am compelled to say, a model for the owners of private wells in this respect.

Vaccination

In Bathurst.

In the town of Bathurst vaccination was only carried on from June to November owing to the illness of the Public Vaccinator. In this period there were 378 children operated on with 271 successes. Vaccine on ivory points was the variety used; the lymph supplied was not very active, the majority of the successes being obtained from arm-to-arm vaccination. With a special supply of experimental lymph I had only 50 per cent. of successes.

In the Protectorate.

The Protectorate Medical Officer vaccinated 60 people, of whom only 30 were successful. He was stationed at Sallikeni, on the north bank, for three months, where the people strongly objected to being vaccinated, and could not be persuaded to undergo the operation. Two of the Commissioners were supplied with lymph, but no record of results was kept by them.

No. 9.—BRITISH GUIANA.

Medical Report for the Year ending March 31, 1904.

By J. E. GODFREY.

Acting Surgeon-General.

The following report of the Medical Department for the financial year from April 1st, 1903, to March 31st, 1904, for the consideration of his Excellency the Governor :—

The Surgeon-General, Sir D. Palmer Ross, M.D., C.M.G., went on leave on December 28th, 1903. Doctor Widdup, acting medical inspector, acted until my return to the colony on January 13th, 1904, when I was appointed to act as surgeon-general.

The usual financial and statistical returns, reports from the medical officers in charge of public institutions and districts, a special report from Dr. Teixeira on the cases of small-pox treated at the Isolation Hospital, "Best," and the report of the Government veterinary surgeon, are attached to this report.

II.—Public Medical Institutions.

These institutions have been worked satisfactorily and economically during the year.

The following table shows the number of in- and out-patients treated at all institutions, with the exception of the lunatic and leper asylums, there being a decrease of 7,050 as compared with last year :—

Istitution	Beds M.	Beds F.	Beds T.	In-patients	Cured	Relieved	Not Relieved	Died	Remaining, April 1, 1904	Out-patients

The reports and statistical tables from the medical officers in charge of these institutions are attached to this report, and show the satisfactory work performed by each of them.

I take this opportunity of placing on record the assistance I received in the management of these institutions from the medical officers in charge.

A.—Public Hospital, Georgetown.

Additional ventilation was provided in several of the wards. A good deal remains to be done in this direction, but this will have to be carried out gradually.

The latrines attached to B and C Wards have been almost entirely rebuilt, much to the advantage of the institution and the comfort of the patients.

The Röntgen ray apparatus has arrived, and will, I hope, be in full working order in a short time.

The resident surgeon's remarks in his report on the prevalence of ankylostomiasis are to the point, and are well worthy of consideration.

Of the total deaths, 411, or 34 per cent., died within 72 hours of admission.

I am very pleased to have to again record a low death-rate. This has gradually fallen from 14·2 per cent. of the cases treated in 1890 to 9·2 per cent. in 1902-03. In 1890 the number treated was 8,566, with 1,216 deaths. In 1903-04 there were treated 12,952, with 1,192 deaths,

The net cost (medical attendance excepted) per caput was 25·9 cents per diem, which is slightly higher than last year.

The total expenditure for the year was $66,106·39, against $65,345·20 for the previous year; and the revenue $6,224·22, against $8,825·81.

B.—Public Hospital, New Amsterdam.

There were 312 deaths out of 2,438 in-patients, which gives a death-rate of 12·1 per cent. on cases treated.

Of the total deaths, 105, or 33·6 per cent., died within 72 hours of admission.

The net cost (medical attendance alone excepted) per caput was 36 cents per diem, which is less than last year.

The total expenditure for the year was $19,461·77, against $18,021·23 for the previous year; and the revenue $2,034·29, against $1,339·99.

C.—Public Hospital, Suddie.

There were 169 deaths out of 1,409 in-patients, which gives a death-rate of 11·8 per cent. of the cases treated.

Of the 169 deaths, 57, or 33·1 per cent., died within 72 hours of admission.

The net cost (medical attendance alone excepted) per caput was 32·1 cents per diem, which is more than last year.

The total expenditure for the year was $7,860·87, against $7,734.99 last year; and the revenue $331·71, against $230·69.

D.—Public Hospital, Bartica.

There were 26 deaths out of 252 in-patients, which gives a death-rate of 10·3 per cent. of the cases treated.

Of the 26 deaths, 13, or 50 per cent., took place within 72 hours of admission.

The net cost (medical attendance alone excepted) per caput was $1·13 per diem, which is higher than last year.

The total expenditure for the year was $2,136·99, against $2,003·86 for the previous year; and the revenue $59·96, against $48·27.

E.—Public Hospital Morawhanna, and Arakaka Ward.

There were 29 deaths out of 566 in-patients, which gives a death-rate of 5·7 per cent. of the cases treated.

Of the 29 deaths, 11, or 38 per cent., died within 72 hours of admission.

The net cost (medical attendance alone excepted) per caput was 57·2 cents per diem, which is lower than last year.

The total expenditure was $4,238·89, against $3,828·58 for the previous year; and the revenue $897·29, against $817·40.

F.—Lunatic Asylum.

The Medical Superintendent, Dr. Earle, submits an exceedingly interesting report, and one that is well worthy of careful perusal.

The re-erection of the old almshouse buildings has been completed, and very extensive repairs to the other buildings on the male side carried out.

I much regret to say that there is yet a considerable amount of rebuilding to be done; this cannot be avoided, as the buildings are old, and some of them have been pronounced as unsafe by the Colonial civil engineer.

The steady increase in our numbers taxes the accommodation of the asylum to its utmost limits.

The following statement will show the value of the work done at this institution by the attendants and inmates:—

Farm produce	$7,706·74
Bakery, labour value	853·20
Parching rooms	189·48
Laundry	3,250·00
Tailors' shop	224·08
Sewing room	441·13
Shoemakers' shop	132·75
Printers' shop	87·50
Other tradesmen	9,085·00
Total	$18,969·88

The net cost (medical attendance alone excepted) per caput per diem was 17·4 cents, which is higher than last year.

The total expenditure was $51,012·99, against $47,115·36 for the previous year; and the revenue $1,737·02, against $2,561.85.

G.—Leper Asylum.

The buildings are in very fair order; the grounds are well kept, and the inmates always appear cheerful at my inspections.

The medical superintendent has at times to complain of their unruly behaviour.

There were 22 cases of absconding during the year. It will be noticed that all of these are males. The female asylum is completely surrounded with a high galvanised fence. Unfortunately, the male asylum cannot, on account of its position with regard to the Mahaica Creek, be thoroughly enclosed unless at a very large expense.

There were 82 new cases admitted during the year, of which 50 per cent. were East Indians.

The net cost (medical attendance excepted) was 14·1 cents per diem, which is the same as last year.

The total expenditure was $22,030·14, against $21,754·21 last year; and the revenue $27·00, against $22·00 for last year.

III.—District Dispensaries.

These dispensaries are situated as follows:—

Upper Berbice River.—The dispenser in charge is provided with a corial for the purpose of travelling up and down the upper reaches of the river, his residence being at Ida Sabina.

Upper Demerara River.—The dispenser resides at Akyma. He is provided with a corial, and visits when required.

Moruca District.—The dispenser resides at the Mission at Santa Rosa, and is under the direction of the priest in charge.

Potaro.—The dispensary is about eleven miles from the Potaro Landing. The dispenser resides on the premises, and the dispensary is provided with beds for the reception of urgent cases. This building was erected solely on account of the labourers engaged on the Gold Placers in that locality. I regret to say that the large majority of these people do not recognise their obligations as to paying the nominal sum charged for treatment and maintenance.

Pomeroon River.—The dispenser resides at the mission at Cabacaburi, and is provided with a small boat and a boy to assist him, for the purpose of visiting the different grants and homesteads on both banks of the river at stated periods. He is under the direct supervision of Mr. Humphreys, the magistrate of the district; and owing to their combined efforts I am very pleased to record that there has been a marked diminution in the number of cases of yaws. The dispenser is a most painstaking, hardworking officer, and performs his duties in an exemplary manner.

The following table shows the expenditure in connection with the different dispensaries and the amounts collected from those who are able to pay a small fee according to tariff:—

Dispensary	No. of Paying Patients	No. of Police Patients	No. of Poor Persons Treated	Total	Expenditure	Revenue
Potaro	562	36	87	685	$1,045·88	$217·41
Upper Demerara River	457	18	290	765	345·99	106·13
Upper Berbice River	325	—	517	842	359·76	45·63
Pomeroon	293	49	1,688	2,030	583·46	72·96
Total	1,637	103	2,582	4,322	$2,335 09	$442·13

IV.—Prison Hospitals.

At the periodical inspections these have been found to be clean and tidy, and the sanitary condition satisfactory. The reports of the medical officers in charge are published with the annual report of the inspector of prisons.

The following table shows the number of prisoners admitted and the number of deaths in these hospitals during the year:—

	Admitted to Hospital			Died in Hospital		
	Males	Females	Total	Males	Females	Total
(1) His Majesty's Penal Settlement	332	..	332	16	..	16
(2) Georgetown ..	234	24	258	2	..	2
(3) New Amsterdam	38	3	41	..	..	..
(4) Suddie	58	1	59	..	..	..
Total	662	28	690	18	..	18

V.—Onderneeming Reformatory for Boys.

The hospital attached to this institution is in a satisfactory condition, and is always clean and well kept. The report of the medical officer is published with the annual report of the superintendent. The inmates appear to enjoy fair health. The boys suffer chiefly from malarial fever. There was one death during the year.

VI.—Orphan Asylum.

The children appear to enjoy good health. The sanitary arrangements are satisfactory. The medical inspector has the medical charge of the inmates. There were four deaths during the year.

VII.—Almshouse.

The infirmary wards attached to this institution are under the medical charge of Dr. Matthey, who in addition acts as medical attendant to the outdoor poor, surgeon to the police, and health officer for the port. The cases treated are mostly chronic diseases; as this institution, in addition to being an almshouse for the poor and aged, is a home for those suffering from chronic and incurable complaints; as many of these cases from the public hospitals which are not likely to benefit by further treatment, and are unable to support themselves, and for whom there is room, are sent there; this is unavoidable, as it is essential that the beds at different hospitals should be occupied by those who are likely to benefit by hospital treatment.

VIII.—Immigration.

The report and statistical returns of the medical inspectors of estates hospitals are published with the annual report of the immigration agent general.

The are at present fifty estates hospitals, having accommodation for 3,031 patients.

During the year 90,932 in-patients and 24,503 out-patients were treated.

There were 1,483 deaths, which is equivalent to a death-rate of 16·3 for every thousand cases treated.

These figures show the enormous amount of work done by the medical officers and the amount of medical relief afforded by the planters, as it must be remembered that the whole cost, with the exception of the salaries of the medical officers, is paid by them.

It is my pleasant duty to report that the estates' authorities continue to carry our the requisitions of the medical officers and medical inspector in a most willing manner, and in no instance have they resorted to Section 88 of the Immigration Ordinance No. 18 of 1891, which gives them the right to appeal to the surgeon-general; this is most gratifying, and shows their desire to do everything in their power for the welfare of the immigrants under their charge.

I am also very pleased to record that, with only one or two exceptions, all of the estates' hospitals have, by my special request, been provided with good but inexpensive microscopes, which are of the greatest assistance to the medical officers in diagnosing diseases.

Water Storage on the Sugar Estates.

This continues the same as has existed for years, *i.e.*, the water is stored in open trenches. A water supply in this colony is not satisfactory unless provision is made either for collecting and storing rain-water in tanks or vats, or the bringing of water from uncontaminated sources by means of pipes, and storing it in tanks or vats, care being taken to see that the receptacles for its storage are so situated as to make fouling impossible. The system adopted on Plantation Blairmont, by which the rain-water collected from the roof of the factory buildings is stored in a large concrete tank is, in my opinion, the best. I can quite realise that the expense of such a scheme is a serious obstacle; but this could be spread over a series of years by erecting concrete tanks capable of holding say, 50,000 gallons every year or every second year. The advantages to be gained by having pure drinking water are enormous, and would repay the estates. If cholera were to become epidemic in this colony, the want of a water supply, as indicated above, would be very acutely felt.

Colonial Medical Reports—No. 9.—British Guiana (*continued*).

IX.—Quarantine.

The enforcement of quarantine on account of the existence of smallpox in some of the West Indian Colonies and British Guiana has caused considerable inconvenience to the travelling public, and loss to the mercantile community; so much indeed, that on all sides it is admitted that our quarantine laws and regulations require considerable modification to bring them into line with the more enlightened regulations of other countries. His Majesty's Principal Secretary of State for the Colonies, recognising the importance of the subject, summoned a conference consisting of delegates from British Guiana and all the British West Indian Colonies to meet at Barbados on April 21st, 1904. It is to be hoped that the outcome of their labours will be the adoption of a uniform system, and not, as at present, where each place has its own laws and regulations.

Mr. G. H. Richter and myself were nominated as the delegates from British Guiana.

When the year opened the following places, which had been proclaimed by His Excellency the Governor as infected (Section 9 of Ordinance 3 of 1870), were still liable to quarantine restrictions: Barbados, on account of smallpox; Trinidad, on account of smallpox.

The proclamation against Barbados was withdrawn on May 11th, 1903, and that against Trinidad on February 18th last.

Two batches of French refugees, in all ten men, were placed in isolation on arrival in the colony, and all their belongings were carefully disinfected.

No case of yellow fever occurred in this colony.

Fifteen vessels were placed in quarantine at this port during the year under review.

This colony was quarantined on account of the existence of smallpox by Dutch Guiana, Barbados, Trinidad, Grenada, St. Lucia, Windward Islands, and Bermuda.

Trinidad raised quarantine against British Guiana in January last, aud early in March Barbados, Grenada, and Dutch Guiana also removed restrictions, St. Vincent doing so towards the end of the same month.

Surinam reimposed quarantine against this colony on the occurrence of two sporadic cases of smallpox on March 24th.

When the year closed (March 31st, 1904) this colony was being quarantined by Dutch Guiana, Barbados, and Bermuda.

X.—Vaccination.

Glycerinated calf lymph is imported for the use of public vaccinators.

There were 108,860 successful vaccinations during the year.

The amount voted for vaccination for the financial year was $6,000.00, but supplementary votes amounting to $41,313.00 were passed by the combined Court.

The total spent on vaccination for the year was $35,471.00.

Appendix B. shows the number of vaccinations performed in the different districts in the Colony during the year.

XI.—Health of the Colony.

A.—Death-rate.

The death-rate of the whole colony was 28·9 per thousand, and the birth rate 29·3 per thousand, the births exceeding the deaths by 14.

The death-rate for the city of Georgetown and its environs, exclusive of the country patients at the public hospital, was 44·1 per thousand.

The high death-rate of Georgetown points to the existence of some special cause or causes why the death-rate of the city should be so much greater than that of the Colony generally.

I attribute the causes to the following:—

(i.) The insanitary condition and excessive overcrowding chiefly amongst the lower and poorer classes; this means deficient ventilation and light, and the unfortunates who have to breathe the vitiated atmosphere contract all sort of diseases.

(ii.) Tuberculosis is accountable for 13·9 per cent. of the total deaths, and as the percentage of deaths from this disease for the whole Colony is only 8 per cent., it proves conclusively that the excess of this disease is largely due to overcrowding.

(iii.) Excessive infantile mortality; 22·8 per cent. of the total mortality was due to children under one year of age, and 29·1 per cent. to children under five years of age.

(iv.) Want of a proper way of disposal of sewage. the city is in parts saturated with sewage due to the existence of cesspits, which are always a standing danger to the inhabitants, and one of the factors tending to a high death-rate by including bowel complaints.

B.—Infantile Mortality.

The returns of the Registrar-General for the year 1903 reveal a most appalling mortality amongst infants.

The mortality of children under one year of age to every thousand children born was for—

(*a*) The whole Colony	205
(*b*) The City of Georgetown	334
(*c*) The Blacks	238
(*d*) The East Indians	171

There can only be one conclusion, and that is the infantile mortality for the whole colony is excessive (in England it ranges from 130 to 140 for every thousand births), but for the city of Georgetown it is appalling.

The time has certainly arrived for active steps to be taken to reduce this terrible loss of infant life.

In Great Britain and other countries measures have been taken which have been attended with considerable success. They consist chiefly in giving practical lessons to the mothers amongst the poorer classes in the care and feeding of young infants; in the establishment of milk depôts where the milk is first sterilised and then put up in bottles each containing a feed. The milk is sold at almost cost price, or given away free to the very poor.

I am convinced that no progress can be made in reducing the mortality until we adopt some such measures; and mothers and others having the charge

of young infants realise that milk is the proper food and not the so-called pap and other abominations on which the helpless babe is fed.

C.—Smallpox Epidemic.

I regret to say that during the year smallpox, fortunately of a comparatively mild type, prevailed throughout the Colony. The disease was introduced here from Trinidad. The Government, recognising the gravity of the situation, practically gave the Surgeon-General a free hand to cope with the epidemic, the combined Court voting the money to meet the expenses.

In order to give every inhabitant of the Colony the chance of being vaccinated, every medical practitioner was appointed a public vaccinator. In the outlying districts where the services of a medical man could not be obtained, competent persons were appointed.

The Public Health Ordinance requires every local authority to provide hospitals for the treatment and isolation of infectious diseases, and as the local authority for Georgetown, which is the Mayor and Town Council, were unable to obtain a suitable site in the city or its immediate vicinity, the Government permitted the quarantine station at "Best" to be used for that purpose. Benabs were erected and equipped at the expense of the Mayor and Town Council for patients from the city, the Town Council, in addition, paying 25 cents a day for the maintenance of each patient.

Dr. Teixeira, one of the assistant medical officers of the Lunatic Asylum, was placed in medical charge.

Patients from the country were treated at the expense of the Colony in the hospital attached to the quarantine station.

The Mayor and Town Council of New Amsterdam and the Town Commissioner of Bartica erected isolation hospitals at New Amsterdam and Bartica respectively for the treatment of cases in their districts. A few cases were isolated by the medical officers in some of the villages.

In only a few isolated instances did the disease appear on the sugar estates, where the inhabitants are chiefly East Indian coolies. When it did it was always in unvaccinated persons, and did not spread. This was due to the fact that the persons afflicted were promptly isolated and also that the coolies are well protected by vaccination.

Vaccination was made compulsory for all "contacts."

The isolation hospital was closed on March 31st, 1904, the last case having been discharged on February 27th, 1904.

There were in all 1,821 cases of smallpox reported, of which 1,434 were treated at the isolation hospital.

There were 14 deaths, which is equivalent to a death-rate of ·7 per cent.

I append a special report by Dr. Teixeira on the cases treated at the isolation hospital at "Best." This report is most valuable and instructive. I take this opportunity of placing on record the valuable services of Dr. Teixeira, the skill with which he treated the cases under his charge, and his zeal in looking after the welfare of every one attached to the isolation hospital.

All the buildings and furniture of the quarantine station used for the purpose of treating cases of smallpox have been thoroughly disinfected and painted.

Appendix C. attached to this report shows the total number of cases of smallpox reported and the parts of the Colony where they existed.

D.—Malarial Fever.

Malarial fever has been prevalent throughout the whole Colony. Now that it has been conclusively proved that malarial fever is caused by the presence in the blood of the malarial parasite known as the *Plasmodium malariæ*, and that this parasite is introduced by a species of mosquito called the Anopheles, every endeavour should be made to guard against this disease.

The methods that have been most successful up to the present are:—

(*a*) The taking of small doses of quinine.

(*b*) The filling up or draining of stagnant pools of water in which the Anopheles breed.

(*c*) The prevention of inoculation by Anopheles by the use of mosquito nets.

If everyone would fill up in the grounds round their residences all places where stagnant water can accumulate, we should considerably reduce the number of these mosquitoes by abolishing their breeding grounds; vats should be enclosed with mosquito-proof wire netting. The larvæ are often to be found in vases and other ornaments used for flowers in the house. A few drops of kerosene oil would kill them.

E.—Ankylostomiasis.

The presence of this disease, due to an intestinal worm (the *Ankylostoma duodenale*), is now generally recognised. This disease has been and is still being introduced into the Colony by East Indian immigrants. That it is on the increase admits of no doubt.

It is hardly too much to say that this parasite causes more harm than all the other intestinal parasites put together; and it is a well-established fact that persons suffering from this disease are liable to be carried off by comparatively slight ailments, the whole system being so debilitated and undermined.

It is especially prevalent among the East Indian immigrants, and I am convinced the estates are yearly losing a considerable amount of labour by it. While on this point it may be of interest to give the following quotation from Manson's book on tropical diseases:—

"Ankylostomiasis is an important disease from the standpoint of the employer of native labour. The invaliding and inefficiency which it causes among coolies, not to mention the deaths, are often financially a serious matter to the planter and the mine owner. To them any wisely directed expense or trouble undertaken for the treating and controlling of this helminthiasis will be abundantly repaid by the increased efficiency of the labourer."

Mode of Infection.—It is spread through the agency of dejecta of people suffering from this disease, the embryos finding their way into the human alimentary canal either by muddy water or in the mud or dirt adhering to the hands or food receptacles of the workmen. They may also be introduced through the skin,

and in my opinion and that of several of the medical officers who have closely studied the subject, the disease known in this colony as "ground itch" is due to the irritation caused by the embryos working their way through the skin. Persons who work in contaminated fields and trenches are the principal sufferers from "ground itch."

It is therefore essential to prevent fæcal contamination of the soil and water by the depositing of fæces about huts and fields. This can best be done by the establishment of latrines of a simple kind and suited to native habits. I am convinced that we shall never make any marked progress in stamping out this disease until this is done.

F.—Tuberculosis.

This disease, according to the returns at my command, has been the cause of 8 per cent. of the total mortality of the Colony for the year, but there are strong grounds for believing that the mortality is higher than this. That pulmonary tuberculosis is on the increase, especially in the city, is beyond doubt.

The mortality in Georgetown from this disease was 13·9 per cent.

It is, I think, universally known that consumption is an infectious disease due to minute germs called the "tubercle bacilli." The phlegm or expectoration of persons suffering from consumption is laden with thousands of these germs, and it is by this means that the disease is conveyed from one person to another. These germs are released as soon as the expectoration dries, and, mixing with the dust, infect the atmosphere.

G.—Diarrhœa and Dysentery.

These diseases were prevalent throughout the year and accounted for 12 per cent. of the total mortality. They are largely due to insanitary surroundings, unwholesome food, and the want of good drinking water.

XII.—Subsidised Nurse-Midwives in Districts.

The question of the appointment of competent midwives in the rural districts seems to have been first raised in October, 1893, but apparently no action was taken in the matter until 1898, when, in consequence of the high mortality of young infants and the large percentage of still-births the combined Court at its annual session, on the suggestion of the late Surgeon-General, passed a vote of $480 for the purpose of locating and subsidising, by the payment of $5 per mensem, eight certified nurse-midwives in villages and rural districts. This vote has been since passed at each annual session of the Court, but for the present financial year the amount has been reduced to $200.

The object was to induce the subsidised nurses to reside in the rural districts or villages, and to give their services free to paupers and to others of limited means at a reduced fee according to tariff.

After they had established a practice, the subsidy would be withdrawn and given to another district, and so on; the number thus employed never to exceed eight.

About the same time it was suggested that the Medical Ordinance, No. 5 of 1886, should be amended as follows:—

(i.) To call these women nurse-midwives or midwifery nurses.

(ii.) To register such women.

(iii.) To make regulations.

(iv.) To cancel or suspend certificates for misconduct, professional or otherwise.

(v.) To protect duly certified midwives by preventing uncertified women from practising.

(vi.) To arrange for the examination of all women practising for five years and upwards.

On October 16th, 1900, the Medical Ordinance was amended by Ordinance No. 32 of 1900, Sections 6 to 11, in which the above suggestions were embodied, with the exception that all women who, on a certificate of a Justice of the Peace, duly qualified medical practitioner, or Poor-Law guardian, satisfy the Medical Board that they were practising previous to that date, were to be certified and registered.

The experiment so far has been a failure. This I attribute to the following reasons:—

By Section 7 of Ordinance 32 of 1900 every person who could produce a certificate of having practised midwifery prior to the framing of this Ordinance received a midwife's certificate from the Medical Board; the consequence was that a large number of incompetent women who had had no training received these certificates and in a way legalised their position. These were the very persons who should have been debarred, and no hardship could have resulted if they had been given a year in which to qualify. The class of persons on whom these women practise are themselves steeped in the grossest ignorance, and seem to prefer the ignorant and incompetent so-called midwives to those who have been properly trained and qualified.

I propose reorganising the whole system of training midwives, and to establish for that purpose schools at the public hospitals of Georgetown, New Amsterdam, and Suddie, to encourage the intelligent women from different parts of the Colony to undergo the course of study with a view of their returning to their districts as duly qualified. This, in my opinion, is a much better plan than sending women into districts who are unknown to the inhabitants. These women, in addition to being trained as midwives, will be taught how to feed the young infant, and by this means I hope to be able to assist in reducing the terrible infantile mortality of this Colony.

XIV.—Financial.

A.—Public Hospitals.

The expenditure of these hospitals is detailed in Tables 4, 5, and 10 attached to this report.

The net daily cost of each patient resident in the public hospital, excluding the charge for medical attendance, but including medicine for out-patients, varied from 25·9 cents (Georgetown Hospital) to $1.13 (Bartica Hospital).

The total cost amounted to $99,804.91, and the sums paid into the Treasury to $9,547.47; thus reducing the net cost to $90,257.44, as against $96,933.86 and $85,671.70, respectively, last year.

B.—Lunatic and Leper Asylums.

The expenditure of these institutions is shown in Tables 8, 9, and 10.

The total cost amounted to $73,043.13, and the revenue to $1,764.02, making the net cost $71,279.11, as against $68,869.57 and $66,285.72, respectively, for last year.

XV.—General Statistics.

Tables 1, 2 and 3, attached to my report, refer to general statistics in connection with public hospitals.

Tables 6 and 7 relate to the Lunatic and Leper Asylums.

XVI.—Total Expenditure.

The following table shows the total expenditure of the Medical Department of the Colony for the year 1903-04:—

Salaries	Surgeon-General ..	$5,280.00
	Medical Inspector ..	4,319.99
	Medical Officers ..	109,770.80
	Special Medical Officers	6,360.00
	Staff, Surgeon-General's Office ..	3,074.83
Travelling Expenses, &c.	Surgeon-General ..	66.94
	Medical Inspector..	635.08
	Medical Officers ..	9,867.23
Stationery and Messenger, Surgeon-General's Office		380.86
Hospitals		99,804.91
Asylums		73,043.13

REPORT ON CASES OF SMALLPOX TREATED AT THE ISOLATION HOSPITAL AT THE "BEST."

PUBLIC LUNATIC ASYLUM,
BERBICE,
June 28, 1904.

SIR,

I have the honour to submit for your information the following report of the cases admitted to the Isolation Hospital at "Best" during the recent epidemic of smallpox. The hospital was opened on the 8th of April, 1903, with five patients, and I assumed charge on the 25th, when there were 38 patients. The last admission was on the 21st of February last, and the patient was discharged on the 27th.

The total number of cases by the Register was 1,434, of which 566 were males and 868 females. It will thus be seen that female admissions preponderated greatly over the male, and this may be accounted for (1) because they are more sedentary and "stay-at-home" in their habits; (2) because they are brought more into contact with the disease from nursing and meddlesome curiosity; and (3) from their more rabid aversion to vaccination. The males, on the other hand, live a more outdoor life, and a large number of them under pain of losing their work submit to the operation, however reluctantly.

RACES.

The classification of the various races admitted is shown in the subjoined table :—

Portuguese and other whites	49	or	3·41 %
East Indians and descendants	22	,,	1·53 ,,
Aboriginal Indians	24	,,	1·67 ,,
Mixed races (mainly coloured)	120	,,	8·36 ,,
Chinese	1	,,	·06 ,,
Europeans (born in England)	1	,,	·06 ,,
Blacks	1,217	,,	84·86 ,,
Total	1,434		

East Indians.—Ten were immigrants from India, of which *two* came to the Colony as infants, leaving twelve *Creole coolies.*

The immigrants suffered from the following diseases :

Mod. smallpox	3
Scabies	3
Yaws	2
Psoriasis	1
Chickenpox	1
Total	10

Those of East Indian descent and born in the Colony showed the diseases in table below :

Discrete smallpox	9
Chickenpox	1
Scabies	1
Not sick	1
Total	12

On examination it was found that 10 had never been vaccinated, one had been done recently and successfully (admitted with itch) and the last one was admitted with its mother, but not sick—and was successfully vaccinated at the hospital. The "fractional" admission of East Indian Immigrants appears to me conclusive evidence of the efficacy of vaccination, as it is well known that all of them must be vaccinated before embarking for this Colony. A certain number besides this show from the characteristic pitting that they had previously suffered from smallpox in their own country. Not a few "free" coolies *sought* admission direct at the Isolation Hospital—but besides chigoes and scabies nothing like smallpox was ever seen.

Aboriginal Indians. — Sixteen were admitted for further observation owing to their developing a suspicious rash some days after vaccination in Georgetown. I was at first inclined to the view that this rash might be of the nature of post-vaccinal erythema, as observed in a recent epidemic or rather outbreak in Scotland, but I soon found that everything was against such. For one thing, there was no seeming connection between vaccination and the rash, the post-vaccinal date of the rash was against it and *they all* had the rash, which would have been a phenomenal condition of things. Only those exposed parts of the body showed any marks—and I could come to no other conclusion than that their own explanation was the right one, namely, that the rash was due to mosquito bites and possibly other insects. In support of this view I may state that Mr. Wauklyn in his annual report for 1902 returned seven cases as due to *vermin bites*, or 1·1 per cent. of 607 admitted to hospital but not suffering from smallpox. As, with the exception of three or four, no sign of reaction to vaccination showed on admission, I revaccinated and discharged as soon as a good crop of vesicles became evident at the site of vaccination.

The remaining eight suffered more or less severely from smallpox ; one, Ada S., was in hospital 108 days, the record, and a more or less physical wreck on discharge.

The following table shows the age incidence of those admitted :—

0 to 5	127	or	8·85 %
5 ,, 10	91	,,	6·34 ,,
10 ,, 20	384	,,	26·77 ,,
20 ,, 30	489	,,	34·10 ,,
30 ,, 40	198	,,	13·80 ,,
40 and up	145	,,	10·11 ,,
Total	1,434		

One patient gave her age at 112 ; several were well over 70.

A glance at this table shows clearly that it was essentially adults who were treated for smallpox at the hospital. Infants suffered severely as a rule.

The number of persons who on admission were vaccinated is as follows :—

Vaccinated in infancy	59	or	4·11 %
,, childhood	56	,,	3·90 ,,
,, under ten years ago	57	,,	3·92 ,,
,, over ,, ,,	2	,,	·18 ,,
,, during incubation period	29	,,	2·02 ,,
	203		
Never vaccinated	1,231	,,	85·84 ,,
Total	1,434		

Of those vaccinated "under 10 years ago" twenty-three were done unsuccessfully, and twenty-one successfully *during* the epidemic.

Twenty-nine were vaccinated during the incubation stage of smallpox, the time varying from a few hours to a few days prior to the onset of symptoms of invasion. Although the disease was unmodified where the vaccination had been successful, the two conditions ran their course together, in some instances the vaccination appeared to become aggravated and the resulting scars assumed a keloid form. In some of the *successful* cases the resulting cicatrices were not only not foveated but appeared to me unsatisfactory and of little value as protection against the prevailing disease.

Diseases, other than smallpox are shown below—and I have also included in the table 39 cases in which no ascertainable disease could be made out.

Yaws	Varicella	Scabies	Lichen	Measles	Syphilis	Marasmus	Acne	Mod. smallpox	Not sick
3	18	7	4	1	1	1	2*	28	39

* The same case readmitted.

This gives a total of 104, to which must be added 285[1] cases of confluent smallpox and 1,045[1] of the discrete form of the disease, to bring the total to 1,434.

[1] On 1,330 cases of smallpox { 21·42 % / 78·57 ,,

The total number of smallpox cases therefore is 1,330. The case of marasmus was that of an infant admitted with its mother and died soon after admission. The case of acne[1] was that of a youthful adolescent with evidences of his dirty habits in the form of scabies and chigoes as well as acne. The acne was the typical acne seborrhoea or "blackheads."

I vaccinated the case of secondary syphilis with success, and there was no doubt as to the nature of this disease. The case of measles was in a child that had been successfully vaccinated by Dr. Wishart recently.

With the exception of the case of yaws, it is somewhat remarkable that the table above shows a similarity of diseases (other than smallpox) as given in Mr. Wauklyn's table in his report previously mentioned.

As not sick I include children admitted with their parents and *vice versâ*: I have placed modified smallpox perhaps wrongly on list, but I wished to account for the remaining cases of smallpox pure and simple. The symptoms of invasion, &c., of modified smallpox are exactly similar to those of the unmodified disease, the main distinction being in the behaviour and course of the rash subsequent to their appearance, and of course the much reduced mortality. I saw no case of recurrence of the disease in the same patient.

Boils	51	Severe—many others—attention not drawn because trivial.
Adenitis	161	Painful glandular enlargements, some suppuration, especially in groins.
Orchitis	8	In adults and the aged.
Conjunctivis	16	One case of marked ulceration of cornea—several mild keratitis.
Abscesses	97	Generally of thigh.
Tuberculosis	1	Probably pre-existent, but agravated and ending rapidly fatal.
Bright's	7	Albuminuria with œdema of limbs refractory to treatment.
Paresis of bladder	2	Temporary, with some paraplegia and incontinence.
Pneumonia	3	One death.
Delirium	3	One death—John Henry, probably case of hæmorrhagic smallpox.
Sloughing abscess	5	Of considerable magnitude with much asthenia.
Mammary	4	With one death, abscess a complication (phagedæna).
Enteritis	6	Well-marked diarrhœa, in convalescence.
Menorrhagia	1	With much dysmenorrhœa.
Cervical cellulitis	1	Very bad case, operation performed.
Abortion	1	Four months pregnant.
Pleurisy	1	Dry—not severe.
Œdema of larynx	1	With some glossitis, much dyspnœa and oppression.
Alopecia	1	Marked baldness in a case of confluent smallpox.
	370	Or 27·81 per cent. of smallpox cases (1,330).

The number and nature of *complications and sequelæ* as noted by me are given above. Under "abscesses" I have included multiple abscess as well as single. Where delirium is mentioned I mean delirium after admission. Many patients had this symptom before they were sent into hospital as well.

These complications are quite characteristic of smallpox.

I have omitted to include in this list the cases of *mania*, in all 5; three recovered in time to be discharged from the hospital, two were sent to the public Lunatic Asylum. I understand there are at present two more in this institution, one having become insane some time after her discharge from the "Best"; the other soon after recovery in her own home (*had smallpox at home and not sent to isolation hospital*). Further, I may observe that *hysteria* was not an uncommon condition noted during convalescence in females.

Vaccinations.

Altogether 287 vaccinations were performed by me at the isolation hospital. From this number, however, must be deducted 52 done on labourers, artisans, and others employed temporarily within the precincts of the station. Of the remaining 235, the successful cases amount to 64, the unsuccessful 166, and doubtful 5. The successful cases include admissions in which nothing in the nature of smallpox was diagnosed, children admitted with their parents, but without sign of disease on them, or parents with sick children, &c. These were, as stated in my first report, used as controls against the unsuccessful cases (all of which were persons convalescing from smallpox). It is evident that 64 cases were saved from smallpox by vaccination at the hospital.

[1] Vaccinated successfully.

Colonial Medical Reports—No. 9—British Guiana—(*continued*).

Deaths.

The subjoined table shows number, causes, &c., of deaths in the hospital.

No.	Initials	Sex	Age	Date of admission	Date of death	Days in hospital	Cause of death	Remarks
1	A. M.	F.	40	May 24	June 2	9	Pneumonia	In stage of desiccation.
2	J. H.	M.	61	June 15	June 25	10	Confluent smallpox ..	Hæmorrhagic?
3	S. M.	F.	11 days	July 4	July 11	7	(Marasamus and) confluent smallpox.	
4	A. G.	M.	23 days	July 18	July 24	6	Confluent smallpox ..	Malignant form of disease.
5	H. D.	M.	1 day	Aug. 22	Aug. 23	1	Prematurity	Mother with smallpox.
6	R. D.	F.	30 days	Aug. 25	Aug. 30	5	Confluent smallpox ..	Malignant.
7	S. L.	F.	23	Aug. 25	Sept. 4	10	Acute general tuberculosis	Convalescent conf. smallpox
8	D. C.	M.	4	Aug. 7	Sept. 7	31	Malarial coma	Pernicious malaria.
9	R. S.	M.	70	Aug. 14	Sept. 17	34	Senile dementia and diarrhœa.	In stage of desiccation.
10	B. R.	F.	18 days	Oct. 14	Oct. 20	6	Marasmus	Infantile atrophy.
11	M. C.	F.	36	Oct. 2	Oct. 22	20	Confluent smallpox ..	Phagedæna of breast.
12	T. B.	M.	15 days	Oct. 19	Oct. 25	5	Confluent smallpox ..	Malignant.

With the exception of No. 10, all the deaths are attributable, either directly or indirectly, to smallpox. The infants, coloured and one white, turned almost black before they died, and the disease in them was of a very malignant form. The case of tuberculosis ran a very rapid course. According to McCombie, this disease occasionally develops during convalescence from smallpox.

No. 9 was an old vagrant in the stage of senile decay and cerebral softening, with smallpox grafted on an already feeble body.

No. 5, a premature child, but showed no external sign of disease, although the mother suffered severely. No. 1 I attribute to septic pneumonia from pustules in the throat.

The mortality on 1,434 would be ·90 per cent., and on 1,330, ·83 per cent., exceedingly low undoubtedly, but not unrecorded in the literature of epidemics.

But if the mortality is low, the suffering, on the other hand, has been so great that only those who have come into immediate contact with the unfortunate victims can realise it. Hancock, writing on a recent epidemic of smallpox in Iowa, returns the mortality at *about* 1 per cent. Bracken, discussing a "peculiar mild form of smallpox," which appeared in various parts of America, states the striking fact that the total mortality was only a little over 2 per cent., and indeed in some localities without fatal cases. Further, the variation in mortality is well shown in the "American Year-Book of Medicine" (1903), in which the *mean death-rate* from 1880 to 1899 in various countries works out as follows:—

Death-rate per Million.

Germany	Mean	1·8 per million.
Scotland	,,	5·3 ,,
Ireland	,,	9·0 ,,
Sweden	,,	9·3 ,,
Switzerland	,,	22·6 ,,
Holland	,,	24·2 ,,
England	,,	33·8 ,,
Italy	,,	179· ,,
Japan	,,	201·0 ,,
Belgium	,,	206· ,,
Austria	,,	358· ,,
India	,,	475· ,,
Hungary	,,	516· ,,
Spain	,,	605· ,,

The following table shows the number of admissions during the period April, 1903, to February, 1904. From this it will be seen that these were highest in July, and that the months of June, July, August and September account for the bulk of the patients:—

1903.	April	56
	May	151
	June	234
	July	341
	August	312
	September	168
	October	118
	November	40
	December	7
1904.	January	5
	February	2

Concluding Observations.

Pitting was noted in all cases of confluent smallpox and a fair number of discrete. Generally speaking, the pits were *irregular* though well-marked and permanent depressions, and not as typical as the regular foveated cicatrices observed in white skins. I have noticed the same condition in East Indian immigrants. So also it was noticed that depigmentation of the cicatrices about the face was almost *nil* or slight, as compared with white skins. Very little change of colour in black skins could be observed as the papules gradually became pustules. Although in the face typical pits were not common, on the body, on the other hand, notably the limbs, there were several cases of resulting foveated but very shallow cicatrices with absence of pigment.

On Face only.

Elevations.—In a small proportion of cases, confluent and discrete, instead of depressions, marked elevations remained with the falling off of the crusts. I had several opportunities of watching their course, which was in brief this: A thin scab would form on each; after a time it would come off; the process would repeat itself for some weeks and then, after a variable period, the elevations would reach the level of the skin and later would become actual depressions. Trousseau, in his "Clinical Medicine," describes the same appearances.

Blood Examinations.

Leucocytosis.—Although I had not the means of adequate knowledge for carrying out a thorough examination of blood *counts*—still from the little I know it was clear that there was a marked leucocytosis, especially of the mononuclear elements. There was marked increase in the small lymphocytes as far as I could see from the examination of ordinary blood films. As I believe the same appearances are to be seen in chicken-pox, this would be of little avail from a diagnostic point of view. The polymorphonuclear neutrophiles which generally are abundantly found appeared to be much diminished in numbers per film.

Anæmia was not noted as *a leading* symptom, so that blood destruction, either quantitatively or qualitatively, could not have been so marked as might have been expected in an epidemic which in its clinical and external manifestations gave the impression of being severe. As a rule, convalescence, once established, was rapid and complete.

Peeling.—In many cases the palms and soles where the pustules were confluent were cast *en masse*, in some cases the exfoliation being over one-eighth inch thick. The under-surface of the cast skin showed the result of the pustules in the form of a perfect honeycomb, except that the pattern was circular instead of being angular. In these cases the new skin was so tender that for some time the unlucky patients could scarcely walk.

I have the honour to be, Sir,
Your obedient servant,
J. TEIXEIRA, G.M.O.

The Hon. the SURGEON-GENERAL.

ANNUAL REPORT OF THE GOVERNMENT VETERINARY SURGEON FOR THE YEAR 1903-1904.

GEORGETOWN,
May 28, 1904.

SIR,—I have the honour to submit the following annual report for the year 1903-04 :—

During the year 1903-04 epidemics of contagious and infectious diseases were not so frequent as in the year 1902-03. I attribute this not only to the measures enforced under the Contagious Diseases (Animals) Ordinance, but also to the fact that many of the uneducated class, who are owners of stock, are beginning to realise the necessity of quarantine restrictions, &c. In one or two instances they have reported the cases to me themselves, a proceeding unheard of when I first entered upon my duties. I always endeavour to make the owner understand why quarantine restrictions are enforced, the absolute necessity of them, and try to get him to imagine himself in the position of a man whose stock became infected through allowing diseased animals to be at large. Furthermore, I point out how it becomes very much cheaper for him to have his place under the charge of a veterinary surgeon, whose duty it is to make efforts to eradicate the disease, at little or no expense to the owner, whereas unscrupulous persons may be employed to attend to the animals, and try to cure glanders, farcy, &c. These are diseases for which the greatest authorities in veterinary medicine have failed to find a remedy. If mineral tonics are administered they abate the disease for a time, but during that time there is a risk of the contagion spreading to other animals, necessitating their destruction. Had a veterinary surgeon been called in at first such needless loss would have been avoided.

GLANDERS.

In British Guiana, I am pleased to say, cases of glanders are becoming fewer. In England, reports for 1902 and 1903 show a decided increase. The immunity from the disease enjoyed here speaks very highly for the contagious Diseases (Animals) Ordinance, and proves the need for the restrictions we have adopted. By the statistics of cases of glanders in England we see that in 1882 the total number reported was 1,389, while in 1903 the total number reported was 2,490, or nearly double. During the year 1892 there were 3,001 cases of glanders in England. This, I believe, was due to an epidemic of influenza which prevailed. When we remember how the acute febrile disease has the effect of developing latent glanders, and thus converting non-infective into actively infective animals, there seems reason to connect the prevalence of influenza with the rise in the number of horses attacked in 1892.

SEASONS.

During the hot months of the year glanders is most prevalent, but of course in tropical countries this is not so noticeable. The explanation I offer of this fluctuation is that the hot months are more exhaustive, and that fatigue causes premature development of the disease, which might otherwise have continued latent in its pulmonary form. I assume that all visible cases of glanders have previously suffered from nodules in the lungs for at least two or three, and possibly for twelve, months. I know that a febrile condition, especially when accompanied by pulmonary congestion, frequently determines generalisations of the disease, and then the clinical symptoms appear. In Canada the summer and autumn seasons are those in which the favourable conditions for the inhibition of glanders prevail.

METHODS OF SPREAD.

Glanders is spread from horses suffering from a discharge, by means of pails, mangers, nose-bags, water-troughs, &c., or any other intermediate bearer of the active virus.

It is a disputed theory as to whether the disease can be spread by germs floating in the air, but when we consider that dried pus-cells float in the air there is ground to believe that the contagion can be carried in this way from one animal to another. Yet, on the other hand, we must not lose sight of the fact that grooms spend ten and twelve hours a day in infected stables without becoming inoculated. It is said that the floating-germ theory was invented to account for the fact that in an infected stud cases are found in various parts of the stable. This circumstance is more easily explained by contagion from nose-bags, mangers, and pails, and by the constant shifting of horses from one part of the stud to another.

The mysterious horse, showing no signs of disease, that works and eats month after month, whilst horses alongside are infected and destroyed by contagion from it, is an ancient, crusted legend. It dates back from the days when glanders without a nasal ulcer was not acknowledged, and when an enlarged gland, a chronic cough, or an intermittent nasal discharge were not considered symptoms of glanders. It has fallen to my lot to investigate numerous outbreaks of glanders, and rarely have I not been able to find three or four horses showing clinical symptoms which had been overlooked by the owners and attendants. I venture to assert that the horse showing no signs of glanders is a non-infective animal, even though his lungs be studded with nodules. Such a horse, though non-infective, is dangerous, because he may develop clinical symptoms very suddenly, and among them may be one accompanied by an escape of active bacilli.

The spread from stable to stable takes place from the introduction of infected horses which have not developed visible signs of disease, but which subsequently become clinically diseased and infective.

Causes.

Glanders arises only by the introduction into the system of the *Bacillus mallei*, which is found in the discharges from the nostrils, farcy buds, infected glands, and nodules of the lungs.

The bacillus is destroyed when exposed to direct sunlight. It may remain active in clean water for many days. It is destroyed by thorough desiccation, and probably lives nowhere out of the animal body or a bacteriological laboratory for more than three months. It is easily destroyed by the more active disinfectants.

Diagnosis.

Some time ago the diagnosis of some cases of glanders was very difficult, but since the introduction of mallein we need have no difficulty, as an injection will, in 98 per cent. of cases, determine the nature of the disease in twenty-four hours.

Every nasal discharge should be treated with caution until its nature is evident. An unilateral discharge, or a discharge that continues without odour, especially when the appetite remains good, should be considered suspicious. Other aids to diagnosis are: the microscope, cultures on selected media, inoculation of small animals, and Widal's agglutinating test. Some of these are only of value in the hands of an expert bacteriologist. Others require days for their development. Mallein is more trustworthy, more simple, and much quicker. Every *post mortem* that I have performed after the reaction of mallein has revealed typical glanders. Several discussions have taken place lately as to the efficacy of this diagnostic agent, but nothing has been adduced to disprove its value.

Control.

It is only by strict legislation that glanders can be stamped out, and legislation such as ours is what is required.

Anthrax.

There has only been one sporadic case of anthrax throughout the whole year. This is striking testimony for the inoculation theory, a theory the soundness of which has been demonstrated twenty years ago. Being new, some of the inhabitants of this colony were at first reluctant to adopt it. I am not over anxious to adopt new methods, and wait until their usefulness has been well established before urging their acceptance here. Inoculation against anthrax has reduced the mortality in France from 20 per cent. to ¼ per cent. which, I think, is of itself sufficient proof of its reliability.

Anthrax is a most serious disease. Not only does it affect the lower animals, usually fatally, but it is also capable of communication to the human subject. Therefore, anyone who knows, or has reason to suspect, that anthrax is on his estate or premises should not think twice about reporting it. If he fails to notify the presence of the disease it is not too much to say that he may be responsible for the loss of many human lives. It is too grave a matter to be trifled with, and some idea of its virulence can be formed by stating that in the year 1617 over 60,000 persons died in the vicinity of Naples from consuming the flesh of animals affected by this complaint.

Cerebro-spinal Meningitis.

In 1903 there was the sporadic form of cerebro-spinal meningitis among the mules at Pln. Hampton Court. The loss on the estate was considerable.

Board of Agricultural.

The sanitary condition of the Government stock is at present all that could be desired. During the year several epidemics broke out among the fowls, which were speedily eradicated. In February, the shorthorn bull suffered from an attack of congestion of the liver. He has now completely recovered.

Annual Reports of District Medical Officers, 1903.

Medical Report of No. 1. District for the Year 1903.

By G. W. Paterson.
Medical Officer and Health Officer.

The health of the district has been good on the whole. There was a slight epidemic of chicken-pox during the second quarter of the year, and a more severe one of whooping-cough about the same time, which was responsible for some deaths among children. Three cases of typhoid fever came under treatment; unfortunately one ended fatally.

"Eruptive Fever."

The subject of chief interest during the year was the introduction into the district of the "eruptive fever" from Trinidad. The first case was that of a woman, who arrived here on April 5th and immediately developed symptoms pointing to the invasion of the disease; she subsequently infected five others. The disease further effected an entrance on three other occasions, but owing to the experience gained in the first case, as soon as a diagnosis was made, they were isolated and the infection did not spread. An isolation station was established at the Ballast Ground, to which were sent all cases developing the disease; such cases in the first instance came from the town and from St. John's and St. Mark's, and subsequently from the shipping after quarantine had been imposed against Trinidad. Fifteen cases in all were treated at the isolation station. There were no deaths. The station was occupied from April 19th to July 21st, and the average stay of each case was 28·92 days, excluding one convalescent case from a vessel riding at quarantine, which was admitted for eleven days after all the others had already been discharged.

No case was discharged till desquamation, was complete. The average duration of the disease, reckoning from the initial symptoms of the invasion till the completion of desquamation was found to be 34·57 days.

There have been marked divergent opinions among medical men in the West Indies as to the exact nature of this disease, which has given rise to a good deal of discussion generally, some of a very polemic character; but the opinion gained ground with experience that it was variola characterised by the mild nature of the disease; in this view, accepted by the majority of medical men, I concur.

It would be of interest to record the characteristics of the disease as observed here. It was communicable, as demonstrated by the first case introduced conveying the disease to certain inmates of the house. In four cases it developed within fifteen days of contagion, so its incubation period can be placed at some time within that limit, probably fourteen days. The invasion was marked by general malaise, fever and headache, the temperature being generally 101° F.; the presence of backache was not marked; these symptoms lasted for three days, when the rash appeared and the temperature dropped.

The eruption was general, appeared first on the forehead and face, where it was at times very abundant, then on the arms, and during the following days spread over the body, the palms of the hands and the soles of the feet being the last to be affected; its presence in the soles sometimes rendered walking painful for a few days—this occurred about the ninth day—the mucous membrane of the mouth and nostrils was sometimes affected. It did not come out in successive crops on the same part of the body, but merely developed in different localities as it made its appearance. The rash consisted of hard papules which slowly enlarged for three or four days and then became partially vesicular at the apex, while the rest of the papule remained hard and prominent; by the sixth day of the eruption the contents of this vesico-papule presented a yellowish appearance like wax, then the pellicle ruptured and there was only a small amount of secretion inside the vesicle—about this time there might be a slight return of febrile symptoms, with perhaps sore throat or conjunctivitis—soon the vesicular apex became brushed off and a distinct tubercle was left. About the ninth day of the eruption pigmentation began to appear. This was a marked characteristic of the disease, till finally were seen tubercles or macules, paler in their centres than the surrounding skin of the patient, with a very dark areola of pigmentation around their bases. As time went on these tubercles became less prominent and both they and the macules contracted, gradually losing their pale centres, while the pigmentation remained and gave an appearance eventually as if ink had been dashed on the part. This black pigmentation occurred in patients with a black skin; the pigment varied in intensity according to the colouring of the skin, in light skins it would be brown.

There was little or no proper pitting, a roughened condition of skin remained from slight prominences of the tubercles and pin-point holes in the skin. This description applied chiefly to the eruption on the face; on the body and extremities the papules passed into better formed vesicles and finally approached nearer in appearance to a pustule, then gradually dried up and when the pellicles fell off a distinct elevation, not a proper tubercle, or a macule, was left. There was no marked umbilication and no crusts were formed, but fringes of skin, remnants of the old vesicles, gradually separated; this process continued on the average up to the thirty-fourth day of the disease, when the patient was considered free from infection.

From the description given it will be seen that the disease differed from chicken-pox in the character and course of the eruption—the hard papules lying at a deep level of the skin, and vesiculating late and partially only with the resulting tubercles in places; not the characteristic pearly, glassy vesicle of varicella. It differed, again, in the abundance of the rash on the face and in its marked prevalence in the palms and soles and in the length of time the disease took to subside.

From typical smallpox it differed in the great essential that the constitutional symptoms were exceedingly mild in proportion to the amount of rash present—some of these cases had the face and body literally covered with a rash as described above, and yet on the eighth or ninth day, apart from some malaise, were quite cheerful and strong—it differed, again, in the absence of an offensive odour, the absence of crust formation and proper pitting, the absence of marked umbilication and complete pustulation.

The relationship, however, of vaccination to the disease was marked, as will be seen by two sets of experiments: I., dealing with the effect of vaccination in preventing the disease, and II., the failure of vaccination on those who had recently suffered from the disease.

I.—Of eleven inmates of a house, one contracted the disease in Trinidad which developed after returning home. Three submitted to vaccination,

which was successful, and did not contract the disease. One had suffered from smallpox in infancy and did not contract the disease (vaccination subsequently failed in this case). Four would not submit to vaccination and contracted the disease. The remaining two were men, not vaccinated, but who had little to do with the house and did not contract the disease.

II.—Fourteen cases who had suffered from the disease were vaccinated during convalescence and some again subsequently, and in only one case was there a vaccine vesicle produced.

The means adopted for stamping out the disease were as follows:—

(1) Observation of passengers arriving from Trinidad for fourteen days; then later on imposition of—

(2) Quarantine for sixteen days of vessels with crew and passengers from the same port.

(3) Isolation of cases suffering from the disease at an isolation station.

(4) Disinfection (*a*) of vessels with cargo and clothing and bedding of crew and passengers, (*b*) of dwellings in which the disease occurred.

(5) Vaccination or revaccination of contacts.

As a case under observation developed the disease it was sent to the isolation station, all contacts vaccinated and the building disinfected; these contacts would then have to present themselves for inspection daily for sixteen days. At the termination of the quarantine period, if all were well on board, the vessel would be discharged after disinfection; but if a case had occurred it would be transferred to the isolation station, and the vessel would have to ride out a further period of quarantine; this took place on three occasions. While at the isolation station the following local treatment of cases was carried out: the body would be sponged with creolin lotion and then smeared over with boracic or creolin ointment, and each case would be given an antiseptic bath of perchloride of mercury before discharge. The disinfectants used were sulphur for fumigating purposes and perchloride of mercury in solution for disinfecting soiled clothing and bedding.

Quarantine.

During the year quarantine regulations were imposed against Trinidad and Demerara, and that in existence against Barbados when the year began was taken off on May 18th.

The quarantine station was not occupied during the year.

One hundred and forty-nine Bills of Health were issued.

Medical Relief.

The total number of attendances on all classes under the Medical Relief System amounted to 2,773 for the year.

The number of vaccinations successfully performed were 215—several prosecutions had to be undertaken under the Vaccination Ordinance.

The number of deaths certified were 98.

There was one inquest and two *post-mortem* examinations of dead bodies.

Medical Report of No. 2 District for the Year 1903.

By P. F. Macleod.

Richmond Hill,
February 26, 1904.

Besides the facts mentioned in the monthly reports there is nothing of interest to add to this report.

Sanitary Conditions.

The sanitary condition of the district is exactly as it has been for years, no improvement has taken place in the manner in which the people live. No attention is paid to sanitation neither in dwellings nor their surroundings, conditions that to the intelligent mind should be pregnant factors in causing and disseminating disease. Yet the health of the inhabitants does not appear to be much affected thereby.

No disease assumed an epidemic form, and the only disease that mention need be made of was an unusual number of cases of infantile diarrhœa in the months of July and August.

The death-rate in this class was considerably above the normal in these months. Meteorological conditions, improper feeding, and exposure I regard as the principal factors as a causation.

Water Supply.

The want of a water supply in the lower parts of the district is a matter that should receive the consideration of the Government. The inhabitants are entirely dependent on pond-water during the wet season, and in the dry months have to travel miles to secure this necessary article of life, and then it is procured from a source that is liable to contamination.

The attendances for vaccination were fairly regular throughout the year.

Very few cases of yaws came under observation.

Medical Report of No. 3 District for the Year 1903.

By N. S. Durrant.

Morne Gay,
January 30, 1904.

The health of No. 3 District during 1903 was good. In the early part of the year the alarm occasioned by the appearance of a case stated to be one of varioloid varicella in St. George's caused extra efforts to be made to get the people vaccinated. In this district the appeal to the adult population was in vain. All persons coming from infected places were examined daily for a fortnight, but no case, fortunately, developed.

Towards the end of the year whooping-cough broke out, and, as in the case of chicken-pox or measles when it reappears after a number of years, only stops when every child in the district has had the specific complaint.

Judging by the number of new board cottages erected the people are prosperous.

I was absent on vacation leave from April 24th to October 29th, 1903.

The details of the work performed during the six months are:—

Vaccinations	253
Free medical and surgical attendances	512
Labourers attended under Government scale of fees	584
Death certificates	37

Medical Report of No. 4 District for the Year 1903.

By R. D. O'Neale.

Gouyave,
February 15, 1904.

The general health of the district was fairly satisfactory during the whole year, with the exception of the diseases as mentioned below.

Malaria fever was very prevalent, it being entirely absent from the district for only two and a half months, March, April, and half of May. The most severe and greatest number of cases occurred during the month of October. The disease is accountable for fourteen of the certified deaths.

Whooping-cough.—During the year a severe epidemic of whooping-cough disturbed the health of the children; commencing in June, it did not completely disappear until the month of December, and then only from the want of fresh subjects to attack. Although the number of cases attended was large, and the type of the malady, especially at the commencement of the epidemic, severe, the deaths recorded from such a fatal infantile disease were comparatively small, the total number being only seventeen.

Dysentery.—A good many cases of dysentery were attended, but this disease did not during any month of the year assume any epidemic form. The greatest number of cases were attended during the month of October, and the cause and origin of the disease appears in the majority of cases to have been malarial.

Sanitary Condition.—There is nothing of importance to report in the sanitary condition of the rural portion of the district; the condition of the roads leading to some of these villages has already been pointed out by me in my monthly reports, and is worthy of attention.

The sanitary condition of Gouyave may be said to be fairly satisfactory. Although a good deal has been done by the Sanitary and Town Boards with respect to the abatement of nuisances and cleaning of the town, the drainage of the Duncan's Town portion is in much the same condition as pointed out by me in my annual report of 1899, doubtless the carrying out of a proper and efficient system being prevented by the heavy cost it would entail.

Water Supply.—The proposed new water supply to Gouyave will undoubtedly prove a great boon to the inhabitants. A better supply than the present one has been a long-felt necessity.

Vaccination.—Under the head Vaccination the attendance was very satisfactory, 308 successful vaccinations being performed; compared with the previous records of four years this is the largest number performed in any year. The Chaumier's lymph gave most satisfactory results.

Medical Report of No. 5 District for the Year 1903.

By H. Bishop.

St. Patrick's,
February 2, 1904.

Malaria.—The endemic disease malaria formed a large percentage of the cases that came under observation, particularly during the latter half of the year. The disease was not confined to the more swampy localities, but was met with, though less frequently, in the hilly parts of the district. The type was usually the mild quotidian, for which, unless the attack was unduly prolonged, the patient did not as a rule seek medical treatment. Chronic invalidism with organic disease, the result of old-standing malaria, was also frequently met with.

Improper feeding and intestinal parasites were largely responsible for the gastro-enteric disorders so frequently met with among children.

Dysentery.—During the month of August a few cases of dysentery of a mild type were seen. In October the disease again appeared, and there was a steady increase in the number of cases during November, when it threatened to become epidemic. At the end of the year there were still a few cases under treatment. The disease was confined to the St. Patrick's portion of the district. In the more educated classes, where instructions as to diet, which forms a very important element in the treatment of these cases, were faithfully carried out the disease never proved fatal. Among the less educated, either from ignorance or inability to carry out the necessary measures, the number of deaths were quite out of proportion to the mildness of the disease. Children and the aged suffered most severely.

Whooping-cough.—Almost all the children in the district under five years of age suffered from the epidemic of whooping-cough which prevailed during the last seven months of the year. The epidemic *per se* did not cause many deaths, but where concurrent gastro-enteric disorders were associated with it, it certainly aided in bringing about a fatal termination.

Eruptive Fever.—One case of "eruptive fever" occurred at Bonair, St. Mark's. The patient was transferred to the isolation station at St. George's, and vigorous measures were adopted to prevent the spread of the disease. These, happily, proved successful.

Yaws.—The disease "yaws" was only by accident encountered. Those affected never seek medical treatment, the popular idea being that doctors' medicine "cures" the disease too rapidly only to cause it to break out afresh with renewed vigour at a later date.

Consumption.—Consumption was more frequently met with than the climatic conditions would lead one to expect. This in some measure can be accounted

for by the housing of the poorer classes, which in some instances is deplorably inadequate. Small, dark, ill-ventilated, one-roomed huts provide shelter for large families; a condition the reverse of hygienic.

During the first half of the year the health of the district may be said to have been very fair, and if taken as representing the normal standard would make that of the second half, when an epidemic of whooping-cough was raging and dysentery and malarial were unduly prevalent, fall far below that standard.

Sanitary Condition.—The primitive hygienic conditions which obtain in the district, I take it, have always existed, and where the population is scattered did not tend to affect to any appreciable extent the public health. These conditions, however, fall far short of the requirements of towns.

The street gutters of the town of Victoria were not kept in a satisfactory condition during the year. It would seem to require the services of at least two men, constantly employed, to cleanse and maintain them in a sanitary condition. The present arrangement is altogether inadequate.

Water Supply.—The town of Sauteurs has suffered in health from the want of a supply of wholesome water and from its proximity to swampy ground, and in the simple unambitious programme for the gradual improvement of the sanitary conditions of the colony by the reclamation of swampy land it, a large and important centre of population, flanked on either side by swampy ground, has a just claim to prior consideration.

Burials.—Burials were frequent in those places removed from the regular burial grounds. From the Duquesne Valley the dead were never taken to the burial grounds, but interred in the cocoa cultivations there, perhaps in dangerous proximity to houses or water supplies, or at an insufficient depth; no supervision being possible in those cases to ensure a proper burial.

The number of prescriptions issued under the Medical Relief Scheme were:—

Paupers	185
Children under 10 years	817
Labourers over 60 years	86
Police and prisoners	25
Labourers under scale of charges ...	1,213
Total attendances ...	2,326
Number of inquests attended ...	4
,, successful vaccinations ...	270

The lymph supplied gave uniformly good results.

Medical Report for No. 6 District.

By W. A. D. Whiteman.

St. Patrick's,
February 25, 1904.

Sir,—I have the honour to submit my report on No. 6 Medical District for the year 1903. Having, however, only been transferred to this district on April 20th last, I am only able to deal with the last seven months of the year.

Health.

During the period under review the health of the district must be characterised as having been exceedingly bad, and the figures below show the enormous amount of work entailed in consequence.

Eruptive Fever.—On April 20th the police reported a case of this disease at River Sallie, which on examination proved only too true. In consequence of this discovery an isolation station was promptly established just outside the village in the River Sallie old house, and this case, together with three others which subsequently occurred, was there isolated and successfully treated. Having already expressed my opinion as to the nature of the disease in a special report on the subject, and given details as to the measures adopted to prevent its spread in my monthly reports, I will now only express my conviction that in dealing with a similar threatened invasion at any future time the rules and regulations drawn up by the General Board of Health might with advantage be modified to some extent. I am of opinion that one large isolation station should be established in St. George's to which all the earlier cases occurring in the districts should be sent, and only when the disease assumes epidemic dimensions should an attempt be made to establish district isolation stations. I make this suggestion knowing the difficulties attendant on securing suitable buildings for isolation stations, and even when these are secured the further difficulties of complete isolation among so ignorant and unreasonable a populace. With incomplete isolation each district station becomes a huge centre of infection and the danger to public health correspondingly great.

Whooping-cough.—An epidemic of this disease prevailed during the whole seven months under review, and played havoc among the children. Even now, at the date of this report, there are still some cases under observation.

Dysentery.—This disease made its appearance towards the end of June, and spreading slowly but surely, continued up to the close of the year. It started in the lowlands where the water supply is of the worst, and though after a time it became general in its distribution, I cannot modify my previously expressed opinion that the cause of these outbreaks is the impure water supply in certain localities, and under certain conditions the disease must necessarily be a regular annual visitor. That its spread becomes more or less general after a time admits of ready explanation, and does not in any way detract from the value of the theory which I venture to advance.

Malarial Fevers.—During the months of July, August and September various types of malaria were prevalent throughout the district, and several cases of typho-malaria occurred in the higher lands where the water supply is from springs pregnant with decomposing vegetable matter.

Yaws.—This loathsome disease is as prevalent as ever, and yet there are but few applications for treatment, it being accepted by the labouring classes as an unavoidable evil.

Venereal diseases appear to be steadily on the increase, syphilis occupying a very prominent position,

yet it is wonderful to note the want of appreciation of the gravity of the disease on the part of victims.

Sanitation.

As in other districts so in this, the sanitary measures adopted are of the most primitive, there being an utter disregard of the most elementary principles of hygiene. It is, therefore, not surprising that so much sickness prevails, and we can only attribute our freedom from severe epidemics of infectious diseases to Providential protection.

Infant Mortality.—Again, the infant mortality is exceptionally high, due entirely to the want of proper food and care; and in this connection I must draw attention to the undoubted degeneration of the rising generation, a fact that must be patent to the most casual observer, and one of serious import to the future welfare of the Colony.

Burials.—I must once more draw attention to the danger to public health arising from the indiscriminate manner in which the dead are buried. The time is now ripe for legislation on this subject, and even more so for the provision of public cemeteries within reasonable access of the different centres of population. At the present time there are but two in the whole parish of St. Patrick, both situated within the town of Sauteurs, and respectively under the complete control of the officiating ministers of the two predominant religious denominations. Such a state of affairs needs no comment, and no blame could be attached to an ignorant populace for gross errors committed in this direction.

Water Supply.—Water is plentiful throughout the district, but with few exceptions is unfit for human consumption.

Vaccinations.—One hundred and seventy-four vaccinations were performed during the seven months, a result due in the main to the excellent quality of the lymph supplied, and also to the eruptive fever scare and prosecutions for non-compliance with the vaccination ordinance.

The attendances under the Medical Relief Scheme (for the seven months) were as follows:—

Free—Labourers' children	1,797	
Paupers and labourers over 60	687	
Police and prisoners	11	2,495
Payment tickets		943
Deferred payment tickets		469
Total ...		3,907
Vaccinations		174
Deaths certified		133
Grand total ...		4,214

Medical Report for No. 7 District for the Year 1903.

By Edwin F. Hatton.

Grand Bras, St. Andrew's,
January 25, 1904.

Sanitary Condition.—The conditions of the rural part of the district offer very little scope for a sanitary report, as there are no public places, except the roads. The drains along many of these roads contain stagnant water throughout the wet season, and form breeding pools for Anopheles mosquitoes. When these pools are near dwelling houses they are certainly a source of danger in spreading malaria.

Water Supply.—The streams and rivulets from which the poorer classes take their water supply, are also a source of danger in spreading dysentery and typhoid. These streams are constantly polluted by manure and other refuse, which have been thrown under the cocoa, being washed into them, and by the washing of clothes in them.

Overcrowding and absence of light and ventilation in bedrooms, with no conveniences for the disposal of excreta, is the rule in the dwelling houses of the labourer and small peasant proprietors.

With regard to the town of Grenville, I can add nothing to my report of last year. There has been no improvement in the sanitary condition of the town. The local health authority tried to compel the town board to make some better arrangement for the cleaning of fish at the Fish Market, but met with little success, the legal procedure proving too cumbersome. After an unsuccessful prosecution in the police court, the town board did make some slight improvement in the scavenging around the Fish Market, but this is still far from satisfactory.

Vaccination.—Vaccination received a stimulus by the presence of smallpox in some of the neighbouring islands, and some four hundred persons were vaccinated in this district.

Smallpox.—On May 4th a man was found in Paraclete suffering from a mild and abortive form of smallpox. He and the other inmates of his house were isolated. This was done under a regulation of the Board of Health declaring "eruptive fever" to be an infectious disease.

This man had recently come from Carriacou where "eruptive fever" was prevalent.

Recent vaccination seems to have protected the other inmates, *i.e.*, his wife and three young children, as no other case occurred. On June 4th, after burning bedding and clothing, and fumigating the house, he was set free.

Whooping-cough.—Whooping-cough was epidemic in the first half of the year. Dysentery prevailed more or less throughout the year, and malaria during the second half.

Enteric Fever.—A few cases of fever of a typhoid type were seen at the end of the year.

Return of duties performed by the Medical Officer of District No. 7 during the year ended December 31st, 1903:—

Number of prescriptions issued—	
Free	1 624
Payment	1,579
Number of attendances on cases:—	
Of Pauper	369
Of Labourers' children under 10 years of age	1,199
Of police constables and prisoners ...	56
Of labourers under scale of charges ...	1,583
Number of deaths certified	153
Number of vaccinations successfully performed	334

Colonial Medical Reports—No. 10—GRENADA (*continued*).

Medical Report for No. 8 District.

By H. J. L. Bennett.

St. Andrew's,
February 20, 1904.

Owing to Dr. Lang's retirement, I was transferred from No. 6 District to No. 8; but did not commence my duties in St. Andrew's until the end of October, when I returned from vacation leave: this report, therefore, deals only with two complete months—November and December, 1903.

Dysentery.—On my arrival I found dysentery very prevalent; but the disease was in a mild form, and the deaths caused by it were chiefly among the aged and very young. Malarial fever cases were also very numerous, as is usual at that season, most of them occuring in the low lands near the sea: the inhabitants about Soubise suffered most.

Heart Disease.—Comparing my present district with my last one, I soon noticed a great difference in the amount of heart disease in the two parishes; I met with many more cases in St. Andrew's than I did in St. Patrick's, and I consider the cause to be the very steep hills which the people have to climb in No. 8 district.

Cancer.—Cancer is another complaint which seems to be very common in this parish, but the increase is probably a general one throughout the island; for this disease is gaining ground in most parts of the world.

Venereal Disease.—All forms of venereal diseases were frequently seen; the fact of Grenville being a "port of entry" explains the mode of introduction of these complaints into St. Andrew's, for seafaring men are not too careful.

Water Supply.—The greater part of No. 8 district is blessed with an excellent water supply, the reservoir is situated on high and isolated land more than four miles from the town, and after passing through filter-beds, the water is distributed by pipes over a large area of the parish.

Yaws.—The disease "yaws" was often met with, but did not appear to be so common as in St. Patrick's; only once during the two months was I asked to treat a case. The peasants still look upon "yaws" as something their children must pass through, like the changing of their teeth.

Sanitary Conditions.—As in other parts of the island, many insanitary conditions flourish in St. Andrew's. Overcrowding in the houses, exclusion of fresh air, burials in private gardens and cocoa fields, improper feeding of infants, careless disposal of night soil, lack of appreciation of the dangerous nature of the sputa and fæces in certain diseases such as consumption and dysentery, and the dirty habits and utter helplessness of the poorer classes when nursing one another in illness.

During the prevalence of dysentery I was astonished to find how scarce milk was in this district. I attribute most of the mortality in the dysentery cases to the want of this indispensable form of food; it is not only scarce, but the small quantity obtainable is generally fraudulently diluted.

Returns for November and December, 1903:—

Free presciptions	290
Payment prescriptions	270
Deferred payment tickets	13
Paupers	72
Labourers	256
Labourers' children	181
Aged labourers	28
Police and prisoners	2
Deaths certified	23
Successful vaccinations	9
Payments per tariff	119
Total attendances	714

Medical Report for No. 9 District.

By G. N. Alexis.

St. David's,
January 29, 1904.

I took charge of the district in the month of October. During the earlier part of the year it was under the charge, for varying periods, of Drs. Whiteman, Redhead and Cremona.

Diarrhœa.—On taking over the district I met a rather severe type of diarrhœa prevalent among the children, and a large percentage of those attacked died from asthenia and failure of the circulation. Fatal results in the majority of cases have been brought about by improper feeding and nursing; this is not to be wondered at when it is remembered the important part dietary and hygiene play in the treatment of these cases.

There were no other features worth recording.

Medical Report for No. 10 District for the Year 1903.

By Dunbar Hughes.

Carriacou,
March 12, 1904.

I took charge on October 15th, 1903, and during the preceding months the district was under the care of Dr. G. N. Alexis.

Malarial Fever.—These fevers are always endemic in Carriacou, and during the month of November they assumed a more than usual violence, the type was chiefly remittent, and cerebral symptoms were present in all the more severe cases.

Syphilis.—A few cases of primary syphilis, and in some cases tertiary; prompt and continued treatment, usually in hospital, have tended to lessen the spread of this disease. I have adopted the plan of keeping primary syphilitics under hospital supervision and treatment as long as possible; for to treat these cases as out-patients would not be effective, as the sufferers soon notice improvement and discontinue attending for treatment.

Yaws.—Only three cases of this disease have I met with.

Water.—Notwithstanding the fact that the water supply of Carriacou affords every facility for contamination, yet I am happy to say that there has not been a single case of a purely water-borne disease.

The prevailing diseases have been those of the digestive system. The habitual diet of "cuckoo," and the drinking of a water that holds in suspension much siliceous matter may be responsible for this state of affairs.

Children.—Infant mortality in Carriacou is excessively high, and in 85 per cent. of cases death is referable directly or indirectly to dietetic indiscretions.

Soon after birth the hapless infant begins its digestive career by an attack on a pap made of arrowroot and brown sugar or molasses and of the consistency of very thick starch paste, and before "he" has reached the age of five days "he" has received a "soothing syrup" known locally as "Luck," and composed of castor oil, olive oil, honey, and gin.

After the age of six months it continues its existence on "cuckoo."

Facts such as these speak for themselves, and the helplessness of the infants calls on us to intervene between the ignorant kindness of the mother and the infant's life and comfort.

No. 11.—HONG KONG.

REPORT ON THE HEALTH AND SANITARY CONDITION OF THE COLONY OF HONG KONG, FOR THE YEAR 1904.

By J. M. ATKINSON.

Principal Civil Medical Officer.

LAID BEFORE THE LEGISLATIVE COUNCIL BY COMMAND OF HIS EXCELLENCY THE GOVERNOR.

Population.

The estimated population of the Colony for 1904 was 361,206. There were 1,205 births and 6,118 deaths; 495 of these were from plague.

The birth-rate was 3·3 per 1,000, as compared with 3·17 in 1903.

The death-rate was 16·94 per 1,000, as compared with 18·9 in 1903.

The following figures will show the comparison of the death-rate in the Chinese and non-Chinese during the past two years:—

	1903.	1904.
Non-Chinese	16·6 per 1,000	12·48 per 1,000.
Chinese ...	19·1 per 1,000	17·18 per 1,000.

Prevalence of Sickness in the Different Seasons of the Year, and General Character as to the Mildness or Severity of the Diseases Prevailing.

Small-pox.—There were 64 cases notified, as compared with 60 in 1903. The greater number of these, viz., 57, occurred in the first six months of the year; five were imported.

In the month of April handbills were published calling the attention of the Chinese to the fact that the disease was prevalent and free vaccination could be done at the Government Civil, the Alice Memorial and the Tung Wah Hospitals.

Cholera.—A small outbreak occurred during the months of May, June and July in No. 2 Health District, and was confined almost entirely to the coal coolies resident in this neighbourhood; at no time was the disease epidemic.

In all there were 41 cases notified during the year, as compared with 10 in 1903, and 460 in 1902.

Plague.—This disease occurred in a much milder form than usual, 510 cases only being notified, as compared with 1,415 in 1903; this is the fewest number of cases we have had recorded in any one year since 1897.

The diminished prevalence of the disease is especially interesting, as it appears to have been very severe in Canton and the surrounding country; it was especially prevalent in Tong Kun District; at Fu Shan, about 40 miles east of Canton, upwards of a hundred deaths had occurred by the beginning of April, indeed in some of the districts near Canton it was reported as causing more deaths than in any year since 1894. Early in April information was received that the disease was prevalent near Swatow.

As will be seen from the following table, the outbreak commenced in April, it reached its height in June, and a marked decline occurred as soon as the maximum mean daily temperature was reached.

The following table gives the number of cases reported in each month of the last two years:—

	1903.	1904.
January	4	0
February	29	3
March	115	4
April	272	40
May	515	135
June	343	194
July	85	96
August	32	19
September... ...	9	9
October	5	0
November	4	5
December	2	5
	1,415	510

To my mind, one of the most important plague preventive measures is the general cleansing of the Chinese houses, which is now carried out by the inhabitants themselves during the winter months. The fact that we have been able to obtain the co-operation of the people in this way is in a great measure due to the personal interest Sir Henry Blake took in endeavouring to quell the 1903 outbreak.

This commenced in November, 1903, and was finished by the end of February, 1904. During this time over 11,000 houses, containing 34,193 floors, were cleansed by the Chinese, the Sanitary Department supplying the hot water, soft soap, and removing the rubbish at a total cost to the Government of $6,123.

Four days' notice is sent to the occupiers that the time has arrived for their houses to be cleansed, at the end of this time they are visited by the Plague Inspector and if found dirty the sanitary staff take the matter in hand and cleanse the premises.

The Chinese have now come to see the value of this measure, and only in a very few instances did they fail to do it in the allotted time.

Colonial Medical Reports.—No. 11—Hong Kong *(continued).*

At the end of the first cleansing it was determined by the Board to continue it throughout the year, this was done until September, and in this way the Chinese houses were thoroughly dealt with at least two or three times.

In the winter of 1904-1905, the cleansing commenced on November 1st, and was completed by February 1st of this year; during this time 12,677 houses in Victoria, Kowloon, Shaukiwan and Aberdeen, containing 34,193 floors, have been dealt with in this way, and 805 cartloads of rubbish have been removed. The total cost to the Government for the necessary fuel, soft soap, &c., was only 1,131·32 dollars.

The inhabitants are assisted by the Plague Staff, whose services are thus utilised in non-epidemic times.

It is intended to continue this work throughout the summer.

Rats.—Twenty-one thousand nine hundred and seven rats were caught during the year, of these 993 were found to be plague infected.

From Dr. Hunter's researches it is evident that it is the rats which bridge over the period between successive outbreaks; during all the winter months cases of plague-infected rats are found, although the disease is at this time practically non-existent in man. The method by means of which plague is spread from rat to rat and from rat to man has yet to be worked out.

An attempt was made early in the year to kill off the rats with Danysz' virus; the strain, however, must have become attenuated, as although it was freely distributed, and there were evidences of its having been eaten, a fatal effect was not induced.

Seeing the successful results which have been last year produced in the Province of Charente in the South of France by Professor Roux, where the rats were practically exterminated by the fatal epidemic induced by this virus, we have applied to the Pasteur Institute at Paris for a more virulent strain of the virus, and we hope to have better results this year.

If we can only diminish in this way the number of rats and at the same time persuade the Chinese to continue the periodical cleansing, we shall do much, I am sure, to diminish the annual prevalence of plague in this colony.

We cannot expect, however, to be free of the disease until many of the insanitary and filthy dwellings in the crowded quarters of the city have been demolished and reconstructed on approved sanitary principles.

With this end in view the Government is voting an annual sum of money for the resumption of these insanitary areas.

Enteric Fever.—This disease has been somewhat more prevalent, at no time, however, was it epidemic: 129 cases have occurred during the year, as compared with 44 in 1903, and 55 in 1902. Nearly one-half of these occurred during the last three months of the year. Thirty-three of the cases were imported.

Malarial Fevers.—To show the diminution which has occurred since 1900, the year in which anti-malarial measures were instituted, I give the admissions from this class of endemic diseases to the three hospitals whose returns are given in these annual reports for the last four years :—

Admissions from Malarial Fever.

	1901.	1902.	1903.	1904.
Government Civil Hospital	787	349	346	221
Gaol Hospital	98	63	93	59
Tung Wah Hospital ...	508	404	205	210
Totals	1,393	816	644	490

At all these hospitals the diagnosis of this disease is made by means of the microscope.

The annual number of cases of malarial fever at these hospitals has thus fallen in four years from 1,393 to 490; no clearer proof can be required of the efficacy of these measures.

Beri-beri.—This disease has been much more prevalent, 739 deaths having been reported, as against 397 in 1903. An enquiry into this disease is now being conducted by Dr. Koch and the Government bacteriologist, and it is to be hoped that some light will be thrown upon this malady about whose etiology so so little is really known.

Dengue.—There were only 43 cases admitted to hospital, as against 123 in 1903, and 422 in 1902.

The following table gives the number of cases of infectious disease notified in each month of the year :—

Disease	Jan.	Feb.	March	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Total
Plague	3	4	40	135	194	96	19	9	...	5	5	510
Small-pox	3	14	24	10	6	3	1	1	...	...	2	64
Enteric fever	3	19	8	3	6	8	6	10	3	17	34	12	129
Scarlet fever	1	...	...	...	...	...	...	...	...	...	...	1	2
Diphtheria	1	...	...	...	...	1	...	...	2	1	1	...	6
Puerperal fever	...	...	...	...	1	1	1	...	...	...	1	2	6
Cholera...	...	...	1	...	16	19	5	...	...	...	...	...	41

General Sanitary Condition of the Colony.

Marked improvement may be noted as evidenced by the diminution in the death-rate for the past three years as shown by the following figures, by the milder outbreak of plague last year, and by the diminished incidence of malarial fever.

	Death-rate per 1,000. 1902.	1903.	1904.
Chinese	21·93	19·1	17·18
Non-Chinese	19·00	16·6	12·48

The steady enforcement throughout the year of the overcrowding and cubicle sections of the Public Health Ordinance must have had a beneficial effect.

During the past year the Government has resumed at a cost of $200,000 an insanitary block of 38 houses in one of the most overcrowded parts of the city; this lot is bounded on the north by Gough Street, on the east by Aberdeen Street, on the south by Kau U Fong, and on the west by On Wo Lane.

The following have been erected and opened during 1904 :—

(1) A public bath-house at Pound Lane with accommodation for 28 males and 10 females.

(2) A public latrine in the eastern portion of the city; and

(3) Three public latrines in the city.

Vaccinations.

The following vaccinations were performed during the year :—

Colonial Medical Reports—No. 11—HONG KONG (*continued*).

REPORT ON THE INFECTIOUS DISEASES HOSPITAL.

This report on the Infectious Diseases Hospital, together with comments on the cases treated during the year ending December 31st, 1904, is written by Dr. Koch, the Medical Officer, and addressed to the Principal Civil Medical Officer for the Colony.

The Plague Epidemic.—The outbreak of plague, as was generally anticipated, I think, was not of an extensive nature, but the intensity of the disease was comparatively great and the mortality high. Thus of a total prevalence of 510 cases, or perhaps it would be more correct to say that this number of cases was notified, the deaths amounted to 497—a percentage of 97·4, this being only one decimal point lower than the death-rate in 1902, which was the heaviest since the appearance of plague in 1894.

The Variety.—There were 59 cases of bubonic plague admitted and 18 cases of the septicæmic variety. No cases of the pneumonic or the intestinal variety came under treatment. This is naturally too small a number to work with satisfactorily as regards statistics, still it is not uninteresting to consider percentages. The bubonic variety constituted 76·6 per cent. and the septicæmic variety 23·4 per cent. of the cases admitted. Comparing this with regard to the total cases notified, I find that the percentage of bubonic cases is only 63·6 and of septicæmic cases 31·4, the cases of pneumonic plague only constituting about 5 per cent. The difference in the percentages of cases notified and cases admitted for treatment is, I think, due to the fact that to the native mind plague is invariably associated with the presence of a bubo or glandular swelling, and hence probably there is a greater chance of such a case of bubonic plague being taken for treatment or taken away from the colony, whereas the septicæmic variety conveys but a vague impression of the disease and of infectivity and is not brought for treatment, but is only diagnosed at the mortuary.

Pneumonic Plague.—There were no cases under treatment.

Intestinal Plague.—No cases of this variety were admitted, nor indeed did any occur during the year. I think it can be safely stated that of the numerous cases of plague that have been under observation since 1894 in all parts of the world this particular variety has been conspicuous by its rarity. The evidence on its behalf is weak. It should be remembered that the plague organism is not a very resistant one, that heat and sunlight rapidly destroy it, and desiccation caused by a high atmospheric temperature is also rapidly fatal to it. Apart from this, it is known that it is extremely sensitive to the action of mineral acids which have a powerful and rapidly destructive effect on it. Under these circumstances primary infection of the alimentary tract—to constitute the intestinal variety—by infected food seems highly improbable. And this apart from the fact that proof is still needed to demonstrate the presence of the plague organism in the foodstuffs sold in the open market.

Sex Incidence.—Of the 77 admissions, 54 were males and 23 females, giving percentages of about 70 and 30. This ratio is not, in my opinion, expressive of a greater susceptibility on the part of the male sex. The susceptibility of the sexes is alike of the same degree. The difference in the ratio is to be explained on other grounds, most probably concealment and removal of the female sick.

Its Incidence with Reference to Nationality.—All the patients, with the exception of two Indians, were Chinese. Contrary to what obtained last year, no Europeans were admitted suffering from the disease—in point of fact, no European contracted the disease this year.

Age Incidence.—My numbers are not large enough to do anything more than to indicate that in the bubonic variety males were affected between the ages of 16 and 40, and females fairly evenly during the quinquenniads of life up to 70 years. The septic variety prevailed among males principally between the ages of 16 and 35.

Recovery-rate.—Of the cases of bubonic plague, 3 males and 6 females recovered, and of the septic variety, 4 males and no females. This gives a total of 13, a percentage of nearly 17 on the cases admitted. Analysing them still further we arrive at these percentages:—

Bubonic plague ...	Males 8 per cent.	Females 29 per cent.
Septic plague ...	Males 25 per cent.	Females *nil*.

These percentages depend upon numbers too small to generalise from.

Death-rate.—This amounted to 82 per cent. of the cases admitted and gives percentages with reference to the bubonic and septic variety as follows:—

Bubonic plague ...	Males 91·6. ...	Females 71.
Septic plague ...	Males 73. ...	Females 100.

Here, too, these percentages should not be used too implicitly; for instance, only two females suffering from septic plague were under treatment, and both died, giving this enormous percentage. It is quite probable that with a large number under treatment the results would not have been the same.

It will be noticed that the death-rate among those under treatment amounts to 82 per cent., whereas in all cases notified it amounts to 97 per cent. This may be held to demonstrate what is evident, that the care and attention a patient receives in hospital give him a better chance of recovery—with reference to the number we are dealing with, we have a difference of 15 per cent. On the other hand, however, I am inclined to the opinion from the cases which I have had the opportunity of observing both in this hospital and in the Tung Wah Hospital, that the heavy mortality on the total cases notified indicates that the disease appeared in a more virulent form, and that no treatment at present known was likely to have had any beneficial result.

Does Early Treatment on the Onset of the Disease Tend to Direct it to a Successful Issue?—I have drawn up a table showing the duration in days of the illness previous to admission. It will be seen that on the

third day after the onset 12 cases of bubonic plague were admitted of whom 1 recovered, and 2 cases of septic plague of whom also 1 recovered. On the fourth day of illness 16 cases of bubonic plague were admitted of whom 2 recovered, and 2 cases of septic plague which succumbed. The history could not be definitely obtained from 20 cases of bubonic plague, and 9 cases of septic plague. These cases were admitted practically *in extremis*, and I am strongly of opinion that the disease was of very recent onset—certainly not more than four days. It will thus be seen that 61 of the 77 cases were admitted comparatively early, and that active treatment had no effect on them, for only 4 recovered, or a little over 6 per cent. Hence I conclude that the disease was of a much more severe type than in 1903: that in spite of cases having been brought in early general poisoning of the system by the plague organism was developed so early, and was of so intense a character that no treatment could have prevented a fatal issue.

As a corollary I append another table (No. V.) howing the length of residence in hospital of patients who died. It will be observed that 8 died within six hours of admission, 13 within twelve hours, 16 within eighteen hours, 4 within twenty-four hours, 11 within two days, and 4 within three days. Only 7 cases lived for a longer period. Thus 41 cases died within the first twenty-four hours—they were in a hopeless condition, and no treatment however energetic could have availed them. Until a serum is discovered which is as efficient in its action as the antitoxin of diphtheria we must rely upon the natural immunity of the human body to antagonise the poison of the plague bacillus, and in our present state of knowledge we are unable to say how long the bacillus remains in the blood before this immunising action becomes of sufficient potency to neutralise the poison and its action.

The Distribution of the Bubo in Bubonic Plague.—The number of cases of bubonic plague amounted to 76·5 per cent., as compared with 23·5 per cent. of cases of septic plague, that is, a ratio of 3 to 1. As it has been asserted lately that one of the principal avenues of infection is by means of the alimentary tract (through the medium of food), this preponderant proportion of the bubonic variety is noteworthy. That there is direct infection and inoculation by abrasions and wounds of the skin there is no doubt, and it must not be forgotten that it is quite possible for direct inoculation to take place through small wounds whose presence may be lost sight of or may remain undetected. A reaction at the seat of inoculation may not always occur—the infective material may be absorbed and conveyed by the lymphatics to the nearest chain of glands without showing that they (the conveying vessels) are affected in any way. In this way the infection may be carried to the more superficial glands or to the deeper. These glands act as a sort of reservoir in which the bacilli accumulate, practically stagnate and partly die; and should necrotic changes be set up they are entirely destroyed and rendered powerless. During this period they elaborate the protein poison which rapidly diffuses through the lymph channels, is taken up by the circulation and acts in the direction of paralysing the vaso-motor nerves, thus leading to hæmorrhagic effusions, to dilated blood-vessels, and to a dilated and debilitated heart. The principal channel of infection, then, being the skin, it is not difficult to understand on reference to Table VI. that most glandular swellings were to be noticed in the femoral region—31; and in the inguinal region—11, and in both femoral and inguinal regions—7—pointing to infection through that part of the body most likely to come into contact with infectious material, the lower extremities. Glandular swellings in the axillary region occurred in three cases, in the cervical region in 4 cases, and in the cervical region in combination with the femoral region in 2 cases. These cervical buboes I attribute to primary infection of the tonsils, which in such cases were enlarged and painful.

The Diagnosis of Plague.—Since we have become familiarised with using for diagnostic purposes a thick blood film decolourised and stained with a basic dye, as was first adopted here by Dr. Bell, there scarcely has been any hesitation in naming as the plague bacillus all organisms that showed a bipolar reaction, and diagnosing as plague any case in whose blood films, prepared thus, these organisms were found. Such a method of diagnosis is far too summary. This cannot be too strongly pointed out and insisted upon. Bipolar organisms, fairly commonly distributed, exactly like the *Bacillus pestis* microscopically, are very easily mistaken for it. Should a patient present the clinical symptoms of plague and a bipolar organism be discovered in the blood we might safely infer without further tests that it is the plague organism. Should, on the other hand, a bipolar organism be found in a blood film or a smear, and the person shows no other sign suggestive of plague, the presence of the organism is most evidently a contamination. Cases have been diagnosed as plague from the presence of this bipolar organism in a blood film without especial reference to clinical symptoms, and mistakes have occurred even when the greatest pains and care have been taken to avoid the possibility of contamination. The diagnosis of plague is a very important matter and should be based upon a clinical as well as a bacteriological diagnosis, and not upon a microscopic diagnosis alone. In the case of the lower animals equally great care should be taken, and no positive opinion can be accepted unless every bacteriological test has been thoroughly worked out and experimental proof obtained. Otherwise the diagnosis not only violates scientific deductions and accuracy but, what is perhaps an equally grave matter, it causes a scare with regard to fresh sources of infection. It should therefore be recognised that the presence in a blood film or smear from any tissue or organ of a bipolar-staining organism does not necessarily mean *per se* that that organism is the *Bacillus pestis*. During an epidemic of plague, or when the patient presents the clinical symptoms of the disease, we may safely conclude that bipolar organisms found in such films are true *Bacilli pestis*, assuming of course that every care and precaution has been taken in making the film so as to avoid contamination. On the other hand, the absence of the *Bacillus pestis* from such films does not negative the diagnosis of plague when clinical symptoms are present.

The Distribution of the Bacillus Pestis.—It is generally accepted that the *Bacillus pestis* is found in the peripheral blood immediately preceding death, but later researches here show that it may be found also at any time during the course of the illness, thus demonstrating the presence of the bacilli in the general blood stream, practically immediately after infection. During the course of the year I paid some attention to this point, and was struck with the varying results obtained, which I have summarised in Table X., and which I shall briefly note here. I may premise that all the cases examined presented the classical clinical symptoms of plague, and that repeated examinations of slides were made in each case.

Detailing the results of my examination it will be noticed :—

(1) That the *Bacillus pestis* was found in some cases during life, and also after death in all the organs—the heart blood, spleen, liver, lungs.

(2) That in some cases (bubonic plague 6, septic 1) the *Bacillus pestis* was not found immediately before death, though it was found on several occasions previously during the illness.

(3) That in other cases (10 of bubonic plague and 1 septic) no plague bacilli could be found during life, but were found after death in the various tissues and organs.

(4) That in 9 cases of bubonic and 1 of septic plague the bacilli were found at the first examination, but not on subsequent examinations.

(5) That in 1 case of bubonic and 1 of septic plague the bacilli could not be found either during life or after death.

(6) That in 9 cases of bubonic and 3 of septic plague which recovered plague bacilli were found in blood films on their admission.

(7) That in 17 cases of bubonic and 7 of septic plague the bacilli were found *ante-mortem*; no *post-mortem* examination was made in these cases.

(8) That in two cases I found the bacilli in the peripheral blood after convalescence had been fully established.

It would seem natural to conclude from these observations that the presence of the *Bacillus pestis* in the blood—the peripheral blood—is not constant, that it is not to be found on every occasion of examination in the course of the disease, nor is it present always immediately before death. It is undoubtedly a fact that the bacilli are always to be found in the bubo during its early stages, but when suppurative and necrotic changes are set up—when the bubo maturates—they cannot always be found. It would seem that streptococcic infection has dominated the position, and that the swarm of leucocytes ingest the plague bacilli and either destroy them or render them inert. In smears from the spleen I was able to find the plague bacilli in the substance of the phagocytes, and in buboes which matured and suppurated I found the bacilli within the substance of the leucocytes while the cocci of suppuration were free. What value is to be placed, as regards its infectivity, on the presence in the peripheral blood of convalescent cases of the *Bacillus pestis* is doubtful. Whether the bacilli are always present in the blood of convalescents, if not always under what circumstances and in which variety of plague, and finally the length of time they persist after convalescence is established, are questions which require elucidation.

The Treatment of Plague.

Owing to the severe type of the disease treatment was practically hopeless in the great majority of the cases, and in addition a large number were brought in *in extremis*. Different methods of treatment were adopted, and I summarise the results.

(*a*) In the first and earliest method, the administration of carbolic acid in large doses, which apparently gave such satisfactory methods in the previous year, was again tried. The cases were put on 12 grains of the pure acid, made up in a palatable mixture every two hours, and this was continued during the whole course of the illness. Carboluria never developed. Digitalis and strychnine by the mouth and hypodermically were also administered. With such large doses of carbolic acid there is often a feeling of depression, a buzzing in the ears, and a feeling of languor and apathy—"as if you were floating in the air when you closed your eye," as one patient expressed it. When the patient is able to appreciate it, the emetations are objectionable. The results by this method were as follows :—

Bubonic plague.—Cases treated	Males	17
	Females	4
Recovered ...	Males	2
	Female	1
Died... ...	Males	15
	Females	3
Septic plague.—Cases treated ...	Males	9
	Female	1
Recovered ...	Males	2
	Female	0
Died	Males	7
	Female	1

(*b*) On the assumption that a bactericide of sufficient strength injected directly into the circulation might be efficacious, I tried a solution of formic aldehyde prepared in the same strength as Maguire uses it in cases of pulmonary tuberculosis. Only three cases were subjected to this treatment. They were all very severe cases, practically hopeless, so the efficacy of this method cannot be estimated; but I am prepared to try it again when opportunity offers. Fifty cubic centimetres were injected directly into one of the veins of the forearm. The following are the particulars of the cases :—

(1) A Chinese male, aged 42, suffering from bubonic plague, with a well-developed left femoral and left inguinal bubo. He was admitted in a practically moribund condition, was delirious, the pulse was very weak and small, and the tongue dry and brown. Stimulants, alcoholic and other, were freely administered, and an injection of 50 cc. of hæmasepsin given intravenously. He died nine hours after admission. At the *post-mortem* examination plague bacilli were found in the spleen but none in the heart blood or in the bubo.

(2) A Chinese male, aged 28, in an advanced stage of septic plague. Had an intravenous injection of

50 cc. hæmasepsin three hours after admission. Seventeen hours afterwards had an injection of 10 cc. of Yersin's serum. Not the least sign of any improvement. Died twenty-two hours after admission. A *post mortem* was made, and smears taken from the organs, which were thrown away by a misunderstanding, so the presence of the *Bacillus pestis* could not be determined.

(3) A Chinese female, aged 48, suffering from bubonic plague. Has a left inguinal bubo and left femoral bubo. No plague bacilli could be found in the blood. She was a well-nourished woman but was in an extremely weak condition. She was given three injections of hæmasepsin, 50 cc. intravenously, on successive days. After the first injection the temperature went down from 102° to 99·4°, but the next day, after the second injection, it ran up to 104·8°. She rallied somewhat, the temperature came down, and oscillated between 100° and 103°. After the third injection she showed some distinct improvement—the pulse became stronger and she was much lighter. Suddenly, however, she changed for the worse and died from heart failure, sixty-seven hours after admission. At the *post-mortem* examination the buboes were crowded with plague bacilli, which were also found in the heart blood and spleen.

(*c*) *Yersin's Serum.* — Great expectations were formed at one time of the curative properties of this serum. As it is prepared, there would seem to be lacking in its composition a complement which should enable it to neutralise or counteract the protein poison secreted by the plague bacillus. With the hope of supplying this deficiency I mixed with it an equal quantity of serum taken from convalescent plague cases, which presumably contained the immune body. This mixture of Yersin's serum plus immune body would by inductive reasoning be quite as efficient as the diptheria antitoxin. In practice, however, it did not prove so.

(*a*) *Treatment by Means of Yersin's Serum Plus Serum from Convalescent Case of Bubonic Plague.*— Three cases were treated by this method. Yersin's serum 10 cc. was mixed with 10 cc. of serum removed from the vein of a convalescent case of bubonic plague, which showed the *Bacillus pestis* in the blood on admission, but not on convalescence. I detail the results.

(1) A Chinese male, aged 27, suffering from septic plague, and showing plague bacilli in the blood on admission. He was given four injections on successive days. The first noticeable result was that diarrhœa occurred, the motions were yellow and very liquid. This lasted for ten days. The pulse was weak. Two days after the last injection the temperature became subnormal, and he had low muttering delirium, and later showed a tendency to drowsiness. The temperature then went up and kept varying between 98° and 99·6°. The bowels became constipated, and later became regular in their action. The patient then gradually and steadily improved, and was discharged well after fifty-six days in hospital. No plague bacilli were found in the blood on discharge. It is interesting to note that almost immediately after his discharge he contracted beri-beri, for which he was treated at the Tung Wah Hospital, and recovered.

(2) Chinese female, aged 27, suffering from bubonic plague. A well-nourished woman, has a left femoral bubo; is delirious. Pulse fairly strong. Was given injections as above described for four days successively, one injection each day. After the first injection purging set in—the motions were frequent, yellow and watery. This continued for two days. On the seventh day after admission a diffuse cellulitis set up over front of right upper arm, apparently originating from a bruise. The pulse became weaker, the delirium continued. Then purging of the same nature set in again and she died thirteen days after admission, and sixteen days after the incidence of plague. The *post-mortem* examination was interesting. The intestinal tract showed no pathological change, but the usual signs of plague presented themselves. It was noteworthy, however, that no plague bacilli were found in the heart blood, nor in the spleen, liver, bubo, or peripheral blood. They were found in the blood on admission, but were absent from the blood taken immediately before death.

(3) Chinese male, aged 30, was admitted suffering from bubonic plague. He was in a very low condition. Plague bacilli were found in the blood. An injection of mixed serum was given, one into the peritoneal cavity and a second full dose into the substance of the bubo. The next day purging set in—the motions being yellow and loose. This subsided in a day. A little tenderness over the abdomen quickly subsided, but a certain amount of œdema set in around the bubo. His condition seemed to improve a little, but he died on the fifth day after admission. At the *post-mortem* examination no plague bacilli were found in the bubo, spleen, liver, lungs, kidneys, or heart blood. It is worthy of note that no bacilli could be found in the peripheral blood examined immediately before death.

(*b*) *Treatment by Yersin's Serum alone.*—Thirty-two cases of bubonic plague and seven of septic were treated with Yersin's serum. An injection of 10 cc. was made subcutaneously, or into the bubo. The number of injections varied from one to four, as were considered necessary, in each case. The results were as follows:—

Bubonic plague: Recovered, M. 1, F. 5; died, M. 20, F. 6.

Septic plague: Recovered, M. 2, F. 0; died, M. 3, F. 2.

Total under treatment: Bubonic 32, septic 7.

Percentage of recoveries in bubonic cases, 19; in septic cases, 30.

It is difficult to estimate exactly what the effect was of the administration of the serum, owing to the fact that the reaction exhibited by the patient was not of a definite nature. It is a matter of fact there was no amelioration in any direction that would justify me in saying that the serum was to that extent effective. If the patient was delirious the delirium might continue or abate irrespectively of the serum. The effect on the temperature was equally uncertain, in some cases a reduction to the extent of a degree or so might occur, in others the temperature would rise; and so, too, was the effect on the circulatory system—

(To be continued in next Journal.)

Colonial Medical Reports—No. 11—HONG KONG (*continued*).

most uncertain. Locally, around the bubo, when the injection was made in that region, there appeared in some cases slight œdema. As regards its general effect viewed broadly, the marked constitutional and local amelioration which is seen in the case of the administration of diphtheria antitoxin was absent. The addition to the serum of an equal quantity of immune serum (serum from convalescent cases) seemed to produce one marked reaction, namely, a profuse diarrhœa. This was constant in the cases, and was always of the same nature. May this have been an effect on the part of the body to get rid of noxious principles? It will be interesting to watch its effects again under similar conditions. In one particular, however, the administration of Yersin's serum was most interesting. I noticed in some of the earliest cases that when plague bacilli were found in the blood in life, they were absent from the heart blood and tissues after death. In six cases of bubonic and one of septic plague in which the bacillus was readily demonstrated in life, it could not be found in any of the tissues after death—namely, the bubo, spleen, liver, lungs, kidneys and heart blood. In certain other cases—thirteen bubonic and one septic—examination after death revealed the presence of the bacillus in the bubo (in the bubonic cases) in varying numbers—in some swarming, in others numerous, in others a few—and in the same series none could be found in the heart blood in eight cases, none in the spleen in four cases, whilst in the remainder of these cases a few could be found in the spleen. In five bubonic cases the bacilli were numerous in all the organs and tissues after the injections. Thus we see that in nearly 17 per cent. of cases treated by Yersin's serum no bacilli could be found after death, in about 33 per cent. they were absent or appreciably diminished in numbers in the heart blood and spleen. On a consideration of these facts the question suggests itself—does the serum act as a bactericide or as a bacteriolytic agent? Is the absence, or the diminution in number, of the bacilli to be attributed to the action of the serum? I am aware that in estimating numbers in this manner objection may be taken on the ground that the method is not rigidly scientific. I grant that. It is, however, difficult, if not impossible, to reckon in any other way, and at all events whatever the error may be it is uniform. On the whole, I strongly incline to the opinion that the serum is effective in the direction of destroying the plague bacilli within the body, as their absence from the heart blood in about 50 per cent. of the cases shows. Why, then, does it not meet with more success when applied as a means of treatment? The reason probably is that cases of plague do not come under treatment early enough, are not, in point of fact, diagnose dearly enough. In consequence the poison is poured out rapidly from the bacteria and penetrating into the system closely and widely gets out of range of the serum, which is only a bactericide and not an antitoxin, and hence has very little effect, if any, upon the course of the disease. I think, however, that if the treatment of a case were to be undertaken sufficiently early, or, on the other hand, if the constitution of the serum could be suitably modified, the effect of its action would be probably more successful. Acting upon these ideas it is my intention to again use the serum when opportunity occurs. (It is right, I should add, that the serum which I used had been kept in the colony for some time, and that some of it came *via* Suez—two circumstances which may have combined to impair its efficiency to some extent.)

Reviewing the treatment of plague and considering as well other methods which have been applied from time to time, I fear it is impossible to avoid the conclusion that up to the present we have discovered nothing that is really effective, nothing that can rank as a specific in the same way as the diphtheria antitoxin. The use of carbolic acid in heroic doses was not conspicuously successful, and I consider we have sufficient grounds to revise the favourable impression which was formed of it the previous year. The only effective means of treatment we can adopt is to keep up the strength of the patient and at the same time watch the action of the heart and guard against its weakness and failure. Should we be able, by so doing, to tide over a sufficient period of time, the effect produced by the intensity of the poison will be reacted against and ultimately overcome by the formations of antitoxin in the blood, and then the system will be enabled to resist the infection and go on to recovery. Four cases of plague were admitted which had passed the critical stage of the disease without having been treated. They did not require much treatment in hospital beyond that which I have sketched above, and they ultimately recovered. Until we can discover an *anti*-body our treatment cannot be anything but expectant and symptomatic, and, above all, we should refrain from interfering with or thwarting the processes of Nature.

Thus, being impotent as regards treatment, it behoves us to be most careful in preventing the development and spread of plague. The consideration of the means is out of place in this report, but I might summarise concisely what is required to this end—elbow room, fresh air and sunlight.

Clinical Notes.

The Maturation of the Bubo.—I have found in some cases that when the bubo, if it was a solitary one, matured and opened spontaneously and discharged freely, the prognosis was much more favourable and the patient generally recovered. In three such cases I found no plague bacilli in the discharges (although they had been present in the blood), but there were crowds of staphylococci; in another case the pus was sterile. The plague bacilli in such cases seem to disappear, but whether this disappearance is caused by the local leucocytosis I am unable to say. At any rate, the discharging bubo seems to act as a sort of destructive agency for them, and as a consequence the active secretion of the poison must be proportionately modified. Acting upon this idea I endeavoured to imitate the process of Nature, and when suitable cases occurred the bubo was assiduously fomented with hot sublimate solution, and if it matured was opened. Two cases treated like this recovered, many

did not. It may be urged that it is only in mild cases that solitary buboes are present, for I found it convenient to treat in this manner only those cases in which solitary buboes were present; but the number of buboes is not always in proportion to the degree of infection, and as Nature has given the hint, it is worth working on those lines.

The Development of Pustules on the Sites of Bruises.—The following case is interesting as pointing to a possible means of spread of plague. The patient, a Chinese female, aged 35, was admitted in a very low condition. She had a left femoral bubo and tenderness over the left inguinal region. She had been under Chinese treatment and was pinched over the chest and arms, the sites being indicated by symmetrical bruises. There were also two patches of necrosis, one over the inferior angle of each scapula; these were about the size of a florin and were superficial. Whether these were caused in the process of Chinese treatment or whether they were of the nature of bedsores, I am unable to say. The interesting point is that plague bacilli were found in these two patches. On the site of the bruises small papules grew up, which gradually progressed until they became converted into pustules, and in these pustules plague bacilli were found in numbers. Eighteen days after admission the bubo was opened—no plague bacilli could be found in it. Eventually the patient recovered. The point of interest in this case is that one should note a possible means of spread of plague. Under native treatment counter-irritation is applied in cases of plague, and pustles may develop which may contain plague bacilli. These pustules may be ruptured, or they may dry, and crusts with plague bacilli be shed, as happens with dried sputum in tuberculosis, and thus acutely infectious material be wafted about. And there are in this colony sufficiently harmonious congenial surroundings for the growth and life of germs so conveyed.

Subcutaneous Hæmorrhages as a Means of Proprosis.—As is well known, hæmorrhages into organs and tissues are common in plague. They occur as well in the bubonic variety as in the septic. When hæmorrhages take place under the skin of the extremities they become visible as large patches, bluish-purple at first, then brownish-black, and are generally of unfavourable import. In two cases this occurred. The first was a well-nourished Indian police constable in good physical condition, suffering from septic plague. He was admitted on the third day of illness. The temperature kept up between 101° and 105°, fell to 98·8° on the sixth day, and rose again to 105° on the eighth day. At first the pulse was rapid and strong, then the rate fell with the fall of temperature, and later it became softer and dicrotic and weak. He became delirious, suddenly extensive hæmorrhage appeared under the skin of the ankles and elbows, and he died shortly after. The second case was a male, aged 33, suffering from bubonic plague. Large patches of hæmorrhage appeared on the anterior surface of legs and dorsum of feet, also on forearms and around elbows. In about three hours after, death ensued.

Small-pox Supervening on Plague.—The co-existence of two acute infectious diseases like small-pox and plague is noteworthy, and I give short notes of such a case. The patient, a Chinese male, aged 38, was admitted suffering from septic plague. It was the fourth day of the illness, and the usual signs of septic plague were present. The blood examination showed the presence of plague bacilli. Two days after a small papular rash appeared over the body, and the temperature went down to 101° from 102·8°. On the eighth day of illness small-pox was unmistakably developed, the rash becoming typically vesicular and confluent, and affecting the palate and fauces, as well as the palms and soles. He died the next day. He had not been vaccinated. The source of infection could not be traced. In view of the fact that a varioloid eruption has been stated to occur in some cases of plague, it is interesting to note that small-pox may undoubtedly supervene. An error in diagnosis may occur when such an eruption exists, but it can only simulate a mild attack of small-pox. When, however, other signs, all confirmatory, exist—as in this case—there can be no doubt. The course of the plague seemed to be altogether suppressed by the small-pox.

A Case of Plague Terminating in Bronchitis and Progressive Atrophy.—The following case is interesting as showing the depth of debility to which an attack of plague is able to reduce its victim, and the case with which other infective agents are able to obtain an effective foothold and breeding ground. The patient, a Chinese female, aged 17, was admitted on the sixth day of her illness suffering from bubonic plague. She had a right and a left femoral bubo, and plague bacilli in her blood. She was very weak, was delirious, her tongue was brownish and dry, and there were sordes about her teeth. There were two small pustules about $\frac{1}{3}$ to $\frac{1}{2}$ inch in diameter on the right leg, and a small ulcer behind the left knee; from there no plague bacilli could be isolated. Four days after she developed bronchitis. Examination of sputum showed no tubercle and no plague bacilli, the temperature remained persistently high, there was slight dulness in the right base, which quickly passed away. Repeated examinations of sputum showed no tubercle and no plague, and latterly there were no plague organisms in the blood. When this was ascertained to be the case she was transferred on the thirty-second day of her illness to the Tung Wah Hospital. She had three injections of Yersin's serum, and was taking iodide of iron and cod-liver oil. At the Tung Wah the evidence of bronchitis was persistent, and she lost ground steadily, becoming gradually more emaciated and weaker. She died about three months after she contracted plague.

The following is the report of the *post-mortem* examination: The body was extremely emaciated—I have never seen a more emaciated body. There was œdema of the lower extremities, and small bedsores over the trochanters and ischia. The heart was soft and flabby—fatty degeneration. Lungs: in both there was marked evidence of chronic bronchitis. There was slight evidence of tubercle, one or two nodules the size of a bean in the right apex in which tubercle bacilli were present. No pleurisy. About 4 ozs. of clear yellow fluid in each pleural cavity. The liver was diminished in size and weight—about 40 ozs.; it was very anæmic. There was fine cirrhosis and marked iron pigmentation. Gall-bladder was not dis-

tended, the bile was very thick. Spleen small in size, weight 4 ozs., capsule thickened; anæmic; diffuse amyloid; marked malarial pigmentation, but microscopically no parasites. Stomach and intestines normal. Mesenteric glands normal. Kidneys pale and fatty. Pelvic organs normal. Brain normal—glands all normal. No plague bacilli found. This case is interesting as demonstrating a condition of progressive atrophy combined with chronic bronchitis and malarial cachexia. The tubercular progress was not active.

The Formation of Fibrin in Plague Blood.—The blood of convalescent plague patients, as I observed in three cases, is very thin and watery. The percentage of hæmoglobin is diminished and the number of leucocytes increased. Fibrin formation is delayed. In ten instances which I observed it took almost five minutes to form. The percentage of fibrin seems lower than normal. These points, however, I was not able to investigate very thoroughly.

Report of the Superintendent of the Government Civil Hospital.

Dr. J. Bell, the Superintendent of the Government Civil Hospital, submits the annual report for 1904 on the work done in the Government Civil and Maternity Hospitals, with the usual statistical tables.

Police.

There were 707 admissions as against 759 in 1903, the strength being 935 as against 921, or 75·61 per cent. of the force were under treatment as compared with 82·41 per cent. in 1903 and 106·4 per cent. in 1902.

There were 12 Europeans, 89 Indians less and 49 Chinese more admitted as compared with last year. Average stay in hospital per man was 9·2 days.

Table I. gives the sick and mortality rate in percentage of strength for the last ten years.

The following table gives the admissions and deaths from the various sections of the force during the last ten years :—

Year	Europeans	Indians	Chinese	Total Admissions	Total Deaths
1895	90	254	116	466	8
1896	94	370	124	588	14
1897	99	320	107	526	7
1898	87	279	122	488	19
1899	117	421	154	692	16
1900	183	522	215	920	4
1901	202	521	214	937	8
1902	150	479	307	936	2
1903	130	431	198	759	5
1904	118	342	247	707	4

There were 4 deaths as compared with 5 in 1903 and 2 in 1902. Of these, 2 occurred amongst the European section, 1 amongst the Indian, and 1 amongst the Chinese. The causes of death were chronic Bright's (European), pernicious anæmia (Indian), phthisis (Chinese), and cerebral hæmorrhage (European).

There were 21 cases of invaliding—2 Europeans, 8 Indians, and 11 Chinese—the reasons for invaliding being chronic dysentery (1), cirrhosis of liver (1), chronic rheumatism (3), phthisis (3), paresis (1), anæmia (2), beri-beri (6), cardiac disease (2), dementia following head injury (1), debility (1).

Malaria.—One hundred and seven admissions as against 167 in 1903, or 11·55 per cent. of the force were attacked as against 18·13 per cent. The European section suffered to the extent of 7·87 per cent., the Indian 20 per cent., and the Chinese 5·73 per cent.

These figures show a marked decrease and it may be interesting to note that this decrease has been steadily maintained for the last five years. The percentages are as follows : 1900=45·03, 1901=44·69, 1902=19·97, 1903=18·13, and 1904=11·55.

None of the Europeans were in more than once for this illness. Of the Indians 2·81 per cent. had two attacks, 0·28 per cent. three, and 0·28 per cent. four attacks. Three Chinese (0·66 per cent.) had two admittances, and 2 (0·44 per cent.) had three.

The question of relapse in malaria is an interesting one, but not easy to settle in the Tropics, as it is impossible to eliminate the chances of a fresh infection in any particular case, and one's theories regarding the subject can only be speculative. Apart from "crescents," which do not occur in all cases, and which sooner or later die out, no latent form has been discovered *post mortem* to account for the relapse. The fact that out of 127 Europeans none have been in more than once is worth noting. The bulk of the repeat cases (11 out of 17) were from the same station, and only 6 came from different stations. Thirteen came in each time with the same form of malaria and 4 with different forms. The Indian with four attacks came in first with malignant, next with simple tertian, again with malignant, and finally with simple tertian, at intervals of almost exactly a month. The other three with different forms of malaria had first malignant attacks, followed by simple tertian and quartan respectively. These 4 cases must be eliminated from the list of "relapses," as the disease breeds true, so that the number is small out of such a large force. Only 6 cases showed crescents in their blood on admission, and of these only 2 were in twice at intervals of a month and two months respectively.

The following table gives the admissions compared to strength for the more important stations of the New Territory for the past four years :—

	1901.	1902.	1903.	1904.
Sha Tau Kok	30·7	...	15·38	13·3
Ping Shan ...	64·2	7·1	45·45	13·3
Sai Kung ...	28·2	16·6	16·6	50·0
San Tin ...	25·0	...	...	10·0
Tai Po ...	70·0	50·0	33·3	27·2
Tai O... ...	10·0	10·0	11·1	10·0
Sha Tin ...	25·0	...	12·5	33·3
Au Tau ...	121·4	7·6	61·5	50·0
Sheung Shui...	63·6	20·0	9·0	—

This shows a decrease in all stations but three—Sai Kung, San Tin and Sha Tin.

The average number of days spent by each man in hospital for this disease was 5·7 against 7·9 last year.

Phthisis.—Four cases were under treatment as against 13 last year. One died and the others were invalided. Two cases occurred amongst the Indians and 2 amongst the Chinese.

Dysentery.—Twenty-eight cases were under treatment as against 13, a large increase. Of these, 8 were Europeans, 18 Indians, and 2 Chinese.

Beri-beri.—Twenty-three cases, all amongst the Chinese section, as against 9 last year. We are still quite ignorant as to the cause of this peculiar malady, and hospital investigations throw no further light on the subject. None of the cases came from the New Territory or out-stations, the stations responsible being Central (14 cases), Water (4 cases), No. 7 (3 cases), and No. 2 (2 cases).

Typhoid Fever.—No cases of this disease occurred.

The various other ailments call for no special observations.

Table II. gives the admissions and deaths during each month of the year.

Table III. gives the admissions for malaria from each station. Exclusive of certain New Territory stations already dealt with, there is a *decrease* in all stations but four, viz., Mount Gough, Tsat Ttze Mui, Tsim Tsat Tsoi and Sham Sui Po.

Gaol Staff.

There were 73 admissions out of a staff of 125, or 58·4 per cent. against 82·79 in 1903. There were no deaths, but two Indians were invalided—one for phthisis and one for cirrhosis of liver. During the dysentery epidemic in June and July the Indian staff suffered somewhat, 3 and 6 cases being admitted out of 12 and 26 for all causes.

Sanitary Department.

There were 29 admissions as against 34 in 1903. There were no deaths and no invaliding.

Government Civil Hospital.

The total number of admissions was 2,585 as against 2,794 in 1903. The decrease is accounted for owing to its being necessary throughout the year to close one ward for repairs.

The total number of out-patients was 13,706 as against 11,911.

Attached are the following tables :—

Table IV.—Showing admissions and deaths in the hospital during each month.
,, V.—Showing operations performed.
,, VI.—Showing admissions and deaths under respective diseases.
,, VII.—Showing admissions and deaths in the Maternity Hospital.
,, VIII.—Showing varieties of malarial met with during the year.

The following table gives the number and class of patients admitted during the last ten years :—

Year	1895	1896	1897	1898	1899	1900	1901	1902	1903	1904
Police	466	588	529	488	692	920	937	938	759	707
Paying patients	498	632	603	741	764	891	830	931	777	772
Government servants	203	269	227	186	208	266	339	460	319	267
Police cases	319	244	299	306	306	347	348	300	276	262
Free	668	778	742	785	739	569	466	454	646	555
Board of trade	129	87	45	65	25	37	28	25	17	22
Total	2,283	2,598	2,445	2,571	2,734	3,030	2,948	3,108	2,794	2,585

This shows, as compared with last year, a decrease in the number of patients admitted under all headings but Board of Trade.

The admissions and deaths for the last ten years are as follows :—

Year.	Admissions.	Deaths.
1895	2,283	114
1896	2,598	143
1897	2,445	119
1898	2,571	138
1899	2,734	114
1900	3,030	155
1901	2,948	153
1902	3,108	140
1903	2,794	142
1904	2,585	128

Of the 128 fatal cases 31 were moribund on admission and died within twenty-four hours.

The rate of mortality for the year was 4·9 per cent. as against 5·08 last year. The average daily number of sick was 93·94 as against 99·09.

Women and Children.—The number admitted was 238 as against 295. The death-rate was 9·2.

Nationality.

Europeans.—784 were admitted as against 802.

Indians and Coloured.—644 were admitted as against 748.

Asiatics (Chinese and Japanese).—1,157 were admitted as against 1,244.

Only 3 officers of the garrison were under treatment as against 6 last year.

(To be continued in next Journal.)

Colonial Medical Reports—No. 11—HONG KONG *(continued).*

DISEASES.

The following diseases caused the greatest number of admissions:—

Fevers—	
Malarial	221
Febricula	128
Typhoid	42
Dengue	43
Venereal disease...	141
Disease of respiratory system	230
,, digestive system	257
Dysentery	106
Beri-beri	70
Rheumatism	73
Injuries	473
Alcoholism	57

The following diseases caused the greatest number of deaths:—

Diseases of respiratory system... ...	27
Injuries	31
Typhoid fever	9
Beri-beri	8
Dysentery	6

Dengue Fever.—Only 43 cases were under treatment as against 123 in 1903 and 422 in 1902, so evidently the disease is dying out. Almost all the cases occurred in October and November. Various endeavours were made to ascertain the cause but without success.

Malarial Fever.—Two hundred and twenty-one cases against 346 in 1902 and 787 in 1901, so it would appear as if this disease were also on the wane. Two deaths occurred as the result of the disease, both being of the "coma" form. The varieties of malaria met with were:—

Malignant	77·7 per cent.
Simple tertian	14·1 ,,
Quartan	1·7 ,,
Mixed infection	6·4 ,,

The diseases associated with malaria were:—

Dysentery	8 cases.
Beri-beri	2 ,,
Dengue fever	2 ,,
Peripheral neuritis	1 case
Bright's disease	1 ,,
Injuries	1 ,,

There were very few bad "crescent" cases, so that no very systematic trial of drugs against this form could be carried out. Neither iron nor carbolic acid in large doses seem to have any effect. Of those under treatment, 26·8 per cent. were Europeans, 46·7 Indians, 24·2 Chinese, and 2·1 Japanese.

Typhoid Fever.—Forty-two cases with 9 deaths against 28 with 6 deaths last year. The death-rate was 21·4 per cent. None of the cases had a relapse. Of the number treated, 21 were imported, Europeans accounted for 17, Japanese 12, Chinese 8, and Indians 5 cases. The increase amongst the Chinese is worthy of note. There is nothing to say about the treatment, which is purely one of nursing and treating symptoms. As far as our experience goes, no drug is of the least use. Carbolic acid and cyllin were both tried but without reducing the fever in the least, and in several cases upsetting the patients' feeding powers—a serious matter. Cyllin especially they would not take, as "it repeats so much," and this I found to be the case by practical experience. Possibly if coated in a different manner it might be of some use, as theoretically an intestinal antiseptic would be an ideal drug. The difficulty seems to be to find one of any use. B. naphthol and lactic acid were also used. Three cases with rare complications are inserted in the Appendix. Two cases had "green, spinach-like" stools shortly before death. This may be a sign of serious import, though it is not mentioned by the authorities. "Widal's reaction" was sought for in all cases, but it was just as often positive as negative and it is of no use clinically.

Plague.—Only 5 cases came under our notice, 3 of which died before they could be transferred to the Infectious Diseases Hospital.

Phthisis.—Fifty-five cases were under treatment as against 60 last year. Of these, 14 were fatal. There were 14 cases amongst Europeans, 21 amongst Indians, 14 amongst Chinese and 6 amongst Japanese. There is little to say of this serious disease and nothing in regard to treatment. Cyllin was tried internally without the slightest benefit. We have had two or three cases of apparent cures. One, an Indian gaol guard, whilst in hospital lost his fever and cough and the tubercle bacilli disappeared entirely from his sputum, but he returned in two months' time as bad as ever and was invalided. Another, an Indian policeman, came in for severe hæmoptysis with fever and tubercle bacilli in his sputum. He lost all his symptoms completely, but had to be invalided in three months' time for the disease. The third, a European, was admitted as a case of "liver abscess." He had fever, cough, hæmoptysis and a swelling over the left lobe of the liver resembling an abscess. His sputum was full of tubercle bacilli. All his symptoms completely disappeared, and when he was readmitted five months' later for venereal disease he was in perfect health and still continues so. No special treatment was adopted in any of these cases, or it might have been credited with the cure.

Febricula.—One hundred and twenty-eight cases against 96. Every endeavour is made to keep down this list, a refuge when all other causes of fever have been excluded. No doubt a few may be malarial, where owing to the administration of quinine before arrival in hospital the parasities have disappeared from the blood. There are two causes of mild feverish attacks which I have noticed and which I do not think sufficient stress is laid upon, viz., syphilis and constipation. I have now collected a fair number of irregular fevers, occurring in young adults, without any definite symptoms, in which as soon as an anti-syphilitic course of treatment is adopted the fever at once subsides. We have also had several cases in which as a result of chronic constipation a species of auto-intoxication has set in, and after free and thorough purging all symptoms have subsided. These cases present in addition to the temperature a furred

tongue, general malaise, and in some cases complain of general abdominal discomfort or pain in right iliac fossa; in fact, one or two have been sent in as cases of appendicitis. A weekly or bi-weekly action of the bowels being a habit with them, they are surprised when told they are constipated, and still more so when their bowels are opened two or three times daily.

Dysentery.—One hundred and six cases with 6 deaths against 50 cases last year—a serious increase which requires consideration. Of this number, 45 were Europeans, 44 Indians, 13 Chinese, and 4 Japanese.

Whatever be the actual cause in each particular case, there is no doubt that this disease must be classed in the "typhoid" group, *i.e.*, a disease almost solely spread by contaminated water or uncooked vegetables, especially when the latter are watered as they are in this part of the world. It is also significant that the number in which no microscopic cause could be ascertained, and which are placed in the bacillary group, have risen very considerably. Using a continuous water supply as an intermittent one is no doubt responsible for some of the spread of these water-borne diseases, as the vacuum in the pipes at times must be greater than any valve will stand, and so dirt and germs must get drawn into the pipes. The storage of water in all sorts of receptacles and places is probably even more responsible, and lastly, the system of manuring vegetables as employed in this country is not only disgusting but extremely dangerous to health, not only giving rise to serious illnesses, but to a good many minor ailments which are at least unpleasant.

Several of the cases have been very serious ones, necessitating the patients leaving the Tropics for good, or for a considerable time. Two cases were interesting, as from them the incubation period of the disease may be inferred, a somewhat difficult matter in tropical diseases. Both were on their way out from home and were on shore for the first time at Singapore. Forty-eight hours after, at sea, they were attacked with typical dysentery. One, I regret to say, died shortly after admission. The cases were presumably of the bacillary type. The Japanese referred to in last year's report (p. 16) as having amœbæ and ankylostoma eggs in his stool again came in with dysentery and was extremely ill, but nothing was found in his stools. I found that occasionally when magnesium sulphate failed to cure, the substitution of the soda salt proved of immediate benefit.

Divided into apparent causes the cases are as follows:—

(1)	23	cases with	*Amœbæ coli.*
(2)	2	,, ,,	*Cercomonas intestinale.*
(3)	2	,, ,,	*Distoma crassum* eggs.
(4)	8	,, ,,	malarial parasites in the blood.
(5)	71	,, ,,	nothing to be found in stool or blood.

Diphtheria.—Only one case, a Chinese child, was under treatment. The antidiphtheritic serum was used, but the child died from heart failure rather suddenly.

Pernicious Anæmia.—Two cases of this somewhat rare disease here were under treatment. One recovered sufficiently to leave for his home in India, but the other, a policeman, succumbed rapidly.

Hepatic Abscess.—Only one case was under treatment, with a successful result, and the case is published in the Appendix. With the large increase in the number of dysentery cases one would expect more if the theory had anything in it that one was the cause of the other.

Appendicitis.—Three cases were under treatment. Two recovered without surgical interference, and the other after the usual operation was discharged well.

Poisons.—Only one case was under treatment, and that due to lead. The patient, a Chinese storekeeper, recovered after a somewhat prolonged stay in hospital.

Fractures.—The following were treated during the year:—

Femur	5 cases.
Arm	3 ,,
Forearm	6 ,,
Leg	11 ,,
Skull (with 13 deaths)	14 ,,
Patella	1 case.
Scapula	1 ,,
Clavicle	1 ,,
Ribs	1 ,,
Fingers	1 ,,

Dislocations.—The following were under treatment:—

Thigh	1 case.
Shoulder	1 ,,
Elbow	1 ,,
Clavicle	1 ,,

Operations.—There were 283 operations performed during the year. Amongst the more important were:—

Liver Abscess.—Already mentioned.

Amputation through Shoulder-joint.—This was done for injury and was successful.

Ovarian Tumour.—This case occurred in a young Chinese. The patient never rallied from the shock of the operation and died shortly after.

Abdominal Section.—Six cases, all, I regret to say, fatal. They were done for ruptured intestine, intussusception in an adult Japanese, purulent peritonitis, the result of malignant disease of the rectum, and three exploratory. These latter were cases of retro-peritoneal hæmorrhage and a ruptured spleen.

Wound of Abdomen.—Three cases with protrusion of intestines. They all did well.

Extrauterine Fœtation.—This case recovered rapidly. The case being of interest is inserted in the Appendix.

Anæsthetics.—Chloroform was administered 185 times without any fatal result, all by the open method. Local anæsthesia was employed in 29 other cases, cocaine and eucaine alone or with adrenalin chloride and ethyl chloride being used.

Vaccinations.—The following were performed:—

	Successful.	Unsuccessful.	Total.
Primary cases ...	213 ...	0 ...	213
Revaccinations ...	311 ...	115 ...	426
			639

Radiography.—The new apparatus has worked well and been of great use throughout the year. Our best thanks are due to Dr. Jordan for kindly keeping our batteries charged.

Maternity Hospital.

Seventy-two cases were under treatment, the highest yet on record. Owing to lack of space one case was treated in the general ward of the Government Civil Hospital and another was sent to Victoria Hospital. Of this number 47 were paying patients, 13 wives of Government servants, and 12 free. Of the births, 24 were boys and 34 girls. The two fatal cases occurred in Chinese—one suffering from advanced interstitial nephritis, and the other from placenta prævia admitted in a moribund condition.

Fees.—The total fees received in this department were :—

Hospital fees	$33,498 34
Certificates	770 00
Total	$34,268 34

APPENDIX.

RUPTURED TUBAL PREGNANCY. OPERATION. RECOVERY.

A Chinese, aged 27, was admitted to hospital on May 25th, 1904, having been seen three hours previously by Dr. Jordan, who, on the above diagnosis, advised her immediate removal with a view to operation.

On admission patient was very blanched, with a quick-running pulse (156) and complaining of great abdominal pain. The operation was at once proceeded with, Dr. Koch kindly giving chloroform. The abdomen was opened in the middle line and blood and blood clot rapidly cleared out. A fœtus, between fourth and fifth month, was found. The pregnancy had occurred in the right tube close to its entrance into the uterine cavity. The placenta was growing on the uterus. The peritoneal covering around this was incised and the whole sliced off, opening the uterine cavity by a hole which admitted the tip of the little finger. This was closed with six thick silk sutures and the abdominal cavity washed out with saline fluid and closed with silk.

For forty-eight hours the patient's condition was very critical, requiring close nursing and constant stimulation (strychnia, camphor, &c.). The temperature rose on the fifth day to 105°. And the os was then dilated, giving exit to a decidual membrane, which at once reduced the temperature. The abdominal incision healed without any trouble and the patient was discharged on June 13th quite well.

Remarks.—The rate of mortality for this operation being so high, successful cases are worth reporting. It is extremely fortunate for this patient that her husband had the good sense to send for a medical man and to follow his advice. The treatment and the special condition met with are also somewhat out of the ordinary. None of the books at our disposal mention the possibility of the placenta being attached to the uterus, nor what should be the line of treatment under this condition.

TYPHOID FEVER WITH COMPLICATIONS. RECOVERY.

Two Cases with Jaundice and Glycosuria.

(1) European male, aged 32, admitted with fever. Patient was very ill, dry tongue, great restlessness and very tremulous, having been drinking heavily. Jaundice was well marked and the urine, on examination, showed a trace of albumen and sugar (gr. i. to ʒj.). This patient had a very severe attack indeed, being delirious for days, great abdominal distensions, passing his motions in bed and several severe hæmorrhages from the bowel. Jaundice disappeared on the twenty-second day, and the sugar on the seventeenth. His temperature fell to normal on the eighteenth day,

was intermittent for another three days before finally keeping normal. He was seventy-four days in hospital and lost considerably in weight.

(2) Japanese adult, aged 37, was admitted on the eighth day of the fever with a dry, furred tongue, well-marked jaundice, liquid yellow stools and delirium. His urine showed a trace of albumen and sugar (gr. i. to ʒj.). The delirium persisted to the twenty-fifth day. Widal's reaction was positive on the eighteenth day. The jaundice persisted up to the twenty-second and the sugar to the twentieth day.

The temperature was normal on the sixteenth day, and then intermittent up to the fortieth, when he had an alarming hæmorrhage from the bowel and finally remained normal on the fifty-fifth day. The patient spent sixty-three days in hospital.

Remarks. — Both these complications are rare. "Sugar is rarely found in the urine" (Brannan, "Twentieth Century of Medicine"). "Jaundice is a symptom of extreme rarity" (*idem*). Murchison only met with three cases, all fatal. Both of the above cases were extremely ill and tested the nursing to the utmost. The treatment throughout was symptomatic only.

A Case with Acute Dysentery.

A French sailor from Saigon was admitted on July 5th, 1904, with a history of twelve days' fever of a remittent type, accompanied by diarrhœa, furred tongue and general malaise. The fever fell to normal on the twenty-seventh day, and the following day the diarrhœa increased in frequency, the stools being full of bloody mucus with amœbæ. The patient was treated with salines and chloride of calcium, but as the condition did not improve much a daily enema of ipecacuanha ʒij. was given as well. The dysentery was, however, very obstinate to treatment and naturally made the convalescence slow and tedious. The patient eventually recovered and left for France on September 6th.

Remarks. — This association is somewhat rare, though it has been mentioned by various observers. No doubt the double infection was acquired at the same time and the incubation period of the dysentery prolonged by the typhoid infection.

Acute Glossitis following Tonsillitis.

A European female, aged 28, was admitted to hospital on May 20th. She had been under treatment for three days previously for acute tonsillitis with high fever (104°). The day before the temperature fell to normal and swallowing was fairly easy. On the morning of the 20th she first complained of the increased size of her tongue and swallowing again became troublesome. Free incisions were made in the tongue by her medical attendant (Dr. Rennie) and her removal to hospital advised in case further interference should be necessary. On admission her temperature was 101°, the tongue was very foul and much enlarged, protruding from the mouth for about one inch, and the patient was quite unable to talk. Four grs. of calomel were at once given and four-hourly mixture containing V. aconiti ɱii. and liq. ammon. acetat. ʒij., with ice to suck. As the incisions were bleeding freely no further treatment in this direction was adopted.

The condition slowly and steadily improved and in four days' time the patient was able to take semi-solid food and talk. The tongue was now well inside the mouth and half the original size. On the 27th both the tongue and throat were quite normal, and the patient was discharged.

Remarks.—From personal experience and from the literature at our disposal, this condition is evidently a rare one and worth reporting. The condition looked alarming on admission, and in view of the rapid increase in size the possibility of tracheotomy was considered. The free and early incisions no doubt saved the necessity for this serious operation.

Liver Abscess. Operation. Second Operation three and a half months later. Recovery.

A German, aged 43, was admitted on January 23rd, suffering from dysentery, fever and pain in right side. Stools contained blood and mucus, but no amœbæ. Temperature chart was of an irregular remittent type. Liver dulness was much increased downwards and a rub was heard all along right base. Under salines the dysentery ceased in three days, but as the hepatic symptoms continued, on January 29th the liver was explored and an abscess found. This was incised and a tube (silver) inserted. Though the cavity drained well the temperature still ran a remittent course, very suggestive of one or more other abscesses.

The patient being very weak no further exploration was attempted, and the temperature finally fell to normal three weeks after the operation and did not rise again. The abscess healed without trouble. His weight increased from 9 to 10·10½ st., and he was discharged on March 31st.

Readmitted April 9th for ten days suffering from alcoholism. The operation wound was quite firm and he had no liver symptoms.

Readmitted on April 28th suffering from alcoholism, fever and pain on right side. The liver dulness was increased downwards, with tenderness along the lower border of the ribs. The temperature ranged between 99° and 103°, and there was a rub at right base. On May 10th the liver was again aspirated over the site of the previous incision and pus was found. The abscess was a very small one and a tube was inserted. The temperature again kept up for five days, but then fell to normal, and the abscess rapidly healed, and the patient was discharged on June 5th.

He was again in hospital on June 9th suffering from his old complaint—alcoholism—and was discharged on the 17th, having, meanwhile, as he gravely informed us, signed the pledge.

Remarks.—This is somewhat an unusual case and shows how much some patients can stand. He was very ill on both occasions when operated on, and even in the alcoholic visits suffered badly. The case is interesting, inasmuch as the first abscess seemed to be due to the dysentery, which was non-malarial and non-amœbic. Though dysentery is common enough here, liver abscess is comparatively rare, more especially amongst Indians, who, however, suffer badly from dysentery.

Colonial Medical Reports.—No. 12.—Seychelles.

Medical Report on the Seychelles for the Year 1904.

By Dr. Robert Denman.

Chief Medical Officer.

Vital Statistics.—(1) The Registrar's return for the year 1904 gives a total population of 20,418, an increase of 446 over the preceding year.

(2) The birth-rate is stated as 34·92, is higher than for the last seven years, being 31·27.

(3) The death-rate shows a very satisfactory decrease, being only 16·12 per thousand. The average for the past seven years was 17·07.

(4) Infantile mortality has greatly diminished. The number of children who died before they reached the age of five years was only 95.

This compares very favourably with the returns for the five preceding years, which were as follows:—

1903	1902	1901	1900	1891
155	122	148	120	121

This may be accounted for by the large number of children who died in 1903, when most of the sickly ones succumbed either directly or indirectly to the epidemic of measles which attacked nearly all the little ones in the Colony.

(5) The deaths of five centenarians were recorded during the year, one person in South Mahé having reached the ripe age of 114 years.

(6) There were 49 still births and 20 twin births in the twelve months.

Meteorological Statistics.—The mean temperature, taken from observations made twice a day, is 77·66° Fahrenheit. This is the lowest temperature I have recorded as yet, and is 1·38° below the average for the years 1898 to 1903 inclusive, and considering the situation of these islands, only 4·35° south of the equator, it will probably never be beaten. A mean shade minimum of less than 70° was registered for eight out of the twelve months, the lowest being 68·2 in November, which again was one of the three coldest months of the year.

The total rainfall was 107·05 inches, and was well up to the average. More than half of the rain, however, fell in January and November, and these two months were responsible for 53·53 inches between them.

There was a marked scarcity of rain in the five months from March to July, during which period only 5·16 inches fell, and of this quantity 3·66 inches fell in four days in April. The result of this was a drought, which did incalculable damage to the plantations, for not only did vanilla vines and cocoanut trees die from want of rain at the sea level, but those plantations which might, from their higher situations on the mountain sides, have escaped with the help of the dews suffered severely from forest fires, which became very common and caused a great deal of destruction towards the end of the dry weather.

The south-east trade wind, or, as it is called here, the monsoon, broke in the middle of April and continued without interruption until the middle of November. It was stronger than usual, and probably helped to account for the low temperatures which prevailed during these months.

Diseases Prevalent during the Year.

There were no epidemics. On other diseases I have nothing special to report.

There was a certain amount of diarrhœa at the commencement of the rains and towards the end of the dry weather, but the year on the whole was a very healthy one.

(2) The causes of death as registered give no help towards determining the existence of any special disease at any given season. The declarations are most often made by ignorant people, and in most cases without any medical certificate.

(3) Cases of phthisis did better than usual this year owing to the dry weather. I must emphasise the remarks I made last year regarding this place as a health resort for consumptive persons; I do not think that it is possible to find a worse place than Mahé for these cases. In ordinary years the air is too moist, the food is too poor, and the accommodation too rough for them.

(4) On the other hand, cases of malarial fever do very well here. They may have one attack soon after landing; this they soon shake off, and do not get a relapse as long as they remain in the colony.

State of the Town of Victoria.

Scavengering has been more satisfactorily carried out this year. The contractor seems to have profited by the experience of the past few years, and now performs his duties with less inconvenience to the public. Even now the night soil service is far from perfect.

In ordinary years the supply is sufficient for the service of the town. A new "reservoir" has been built higher up on the Lablache River, and the supply to the north end of the town is somewhat improved. The year under consideration tested the capabilities of the supply very severely, and though there was great scarcity for some time towards the end of the very dry weather, the supply was never entirely arrested. The state of affairs was sufficiently grave to make the question of an increased and more reliable supply a very important one, and though the expenses connected with any new scheme may appear to be great, I am of opinion that the money so spent would be well spent, as the town will then be free from all fear of failure of water for drinking, and if the St. Louis river plan be adopted it will also be possible by the judicious arrangements of street hydrants to protect the town against a serious outbreak of fire. At present it may be said to be unprotected, as the two small hand

pumps on carts are quite insufficient to cope with even a small fire.

Reports of the Assistant Medical Officers of South Mahe and Praslin Districts.

These reports are forwarded herewith. They are interesting in that they contain the expressions of opinions formed by their writers after three years, experience in their respective districts. Both of these gentlemen agree with me in noticing the absence of any epidemic during the year, and they both remark upon the great improvement in the general health of their parts of the colony as compared with 1903.

I do not think that the death-rate of 14·08 per mille for Praslin, and 14·01 for South Mahé can be beaten by any other tropical colony.

The difference between the death rates for these two districts and that of the whole colony is partly accounted for by the fact that the Registrar bases his rate on the estimated population at the beginning of the year, whilst that of the outlying districts has been based upon that of the end of 1904, and partly by the fact that a good many of the incurable people from both districts come to town to die.

Vaccination.

Owing to the interruption of the mail service, vaccination had to be suspended for several months. It was resumed as soon as fresh lymph arrived, and the lymph, except that which had continued to be despatched monthly from London during the Marseilles strikes and which have been left lying at that port pending the resumption of the mail service and which was also worthless, was of good quality and gave very good results.

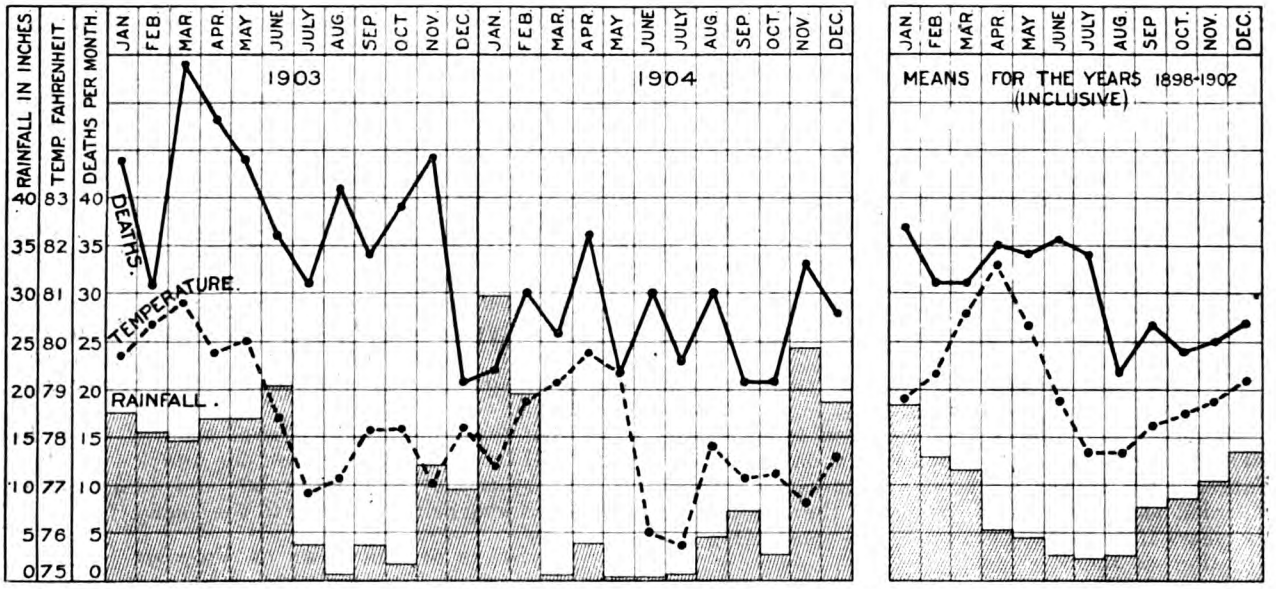
Quarantine Services.

The quarantine station at Long Island was used during the earlier part of the year. At my last inspection the disinfector worked satisfactorily and the houses and stores were in good condition, and the guardian deserves credit for the care he bestows upon the property committed to his charge.

Hospitals and Dispensaries.

No new dispensaries have been opened during the year. The increase in the number of patients requiring free treatment is due to the increased poverty amongst the lower classes, and not to any increase in the amount of sickness.

Two hundred and ninety patients were treated at the hospital during the year, viz., 241 males and 49 females.



Twenty deaths occurred, giving a death-rate of 6·8 per cent., an improvement upon last year.

The combination amongst the whole staff has been very good, the nursing sisters as usual doing excellent work, and earning the golden opinions of the medical officers and the heartfelt gratitude of the sufferers under their care.

MEDICAL REPORT ON SOUTH MAHE FOR THE YEAR 1904.

By Dr. J. T. BRADLEY, ASSISTANT MEDICAL OFFICER.

I have the honour to forward the third Annual Report on South Mahé, first and second divisions.

The year 1904 saw no serious outbreak of any disease like the epidemic of measles in 1903. Measles died out in this district on November 26th, 1903; after that date no further case of measles occurred in the district.

I intend in this report to draw attention to the great number of people who are affected with hernia. From a study of the cases that came under my notice I am of opinion that heredity plays an important *rôle* in this disease. Hernia in Seychelles follows certain lines, and the principal causes in the causation of hernia are as follows:—First, hereditary influence; if the parents have hernia, very often the children develop hernia within the first year of life, at times within a few days after birth. Further, I am of opinion that when hernia is on the male side it seems to be transmitted oftener than from the female side. Second influence is, no doubt, the tropical climate, as it produces a certain weakening of the abdominal tissues; this, combined with the continued climbing of the hilly and mountainous districts, can be looked on as the second important factor.

The other influences are the same as in Europe, viz., strain, unusual exertion, and in the case of women, constipation. Children with hernia are allowed to go about without any special precautions being taken by the parents; the ordinary congenital forms are in males inguinal, in females umbilical. As they grow to adult life these hernias get larger, and are the cause of much suffering and annoyance in after life. A lot of this could be avoided if the parents would only take simple precautions; in the case of an umbilical hernia, by a binder fitting the loins and a small piece of metal covering the hernial opening. In the case of inguinal hernias I always advise the patients to get a small truss at the Victoria Hospital, where they are sold at a reasonable price. Very often, in the case of children, if proper fitting trusses are worn the hernial opening closes up.

The year 1904 had in South Mahé a good many cases of dysentery. This may be due to the great dryness in the early part of the year, followed by the heavy rains at the close of the year.

Pneumonia is, in my opinion, always the most dangerous disease in the Seychelles; during the year 1904 the deaths were four, but the year was singularly free from the disease. I am of opinion that the bulk of deaths uncertified, where the cause is given as fever, are almost always due to pneumonia.

(To be continued in next Journal.)

Colonial Medical Reports.—No. 12.—SEYCHELLES
(continued).

I think there is an improvement in the health of children here. I continually impress on mothers the importance of breast feeding, and in the bulk of the families here no attempt is made now to give food beyond the breast for the first three months of infant life. As a result the infant mortality has dropped considerably. In 1902 the number of children that died under one year was sixteen, in 1903 the mortality was ten, and in 1904 the mortality was twelve. However, in 1904 in this mortality there were, of the twelve children that died, three children that survived birth only a couple of hours.

Vital Statistics.

Further on can be found the attached tables, showing a comparison of the births, deaths, and still-births of the years 1902, 1903 and 1904, also comparative tables of the ages at which death occurred during these years.

I would like to draw attention to the mortality tables, in order to see what is the dangerous periods to life in Seychelles.

For the first year after birth the dangerous period is very marked; roughly speaking, about one-fifth of the deaths occurred in the first year. If a child weathers the first year the zone of danger commences to diminish, but it is still a critical time. From five years to twenty years the danger commences to diminish, but it is a more dangerous period than from twenty to thirty, when the mortality is less. The most favourable period to life is thirty to forty, after forty the dangerous zone commences again. At sixty to seventy the chances are gone down very low; in fact, from fifty years upwards the danger to life is well marked. During the year 1904 there were two very ripe ages recorded, viz., one of 114 years, and one of 100 years.

It is a matter of congratulation the steady decrease in the mortality of children. In 1902 the number of deaths of children under five years was 28, in 1903 the mortality under five years was 21, a decrease of 7, while in 1904 the mortality under five years was 17, a decrease of 4 as compared to 1903, and compared with 1902 a decrease of 11.

Taking the births as 155 for the year 1904, the deaths as 63, the increase in population for the year 1904 is 92. This increase added to the increase in 1902 and 1903 makes a net increase of 293 for these three years.

1901.	Census taken in that year's population	4,203
1902.	Estimated population to December 31st	4,301
1903.	,, ,, ,,	4,404
1904.	,, ,, ,,	4,496

The number of deaths for the year in South Mahé was 63, a diminution of 3 as compared with the year 1903. I think this can be looked upon as the natural state of affairs. A good many deaths were due to old age, as 16 deaths occurred in people under 80 years of age, 3 deaths under 90 years, and 5 deaths over 90 years of age. Of these over 90 years one had reached 114 years, and the other 100 years.

Taking the estimated population as 4,496, this works out a death-rate of 14·01 per thousand, being a diminution of ·97 per thousand as compared with 1903.

The diseases that principally caused death during 1904 are as follows:—Senile decay, 16; dysentery, 5; pneumonia, 4; syphilis, 4; syphilis hereditary, 5; diseases due to endocarditis, 3.

During the year there were 11 still-births. A curious fact is that for the years 1902, 1903 and 1904, there were exactly the same number.

During the year there were 155 births, a diminution of 14 as compared with 1903. The average birth-rate per thousand for 1904 is 34·47, being a diminution of 3·90 per thousand as compared with the preceding year.

Dispensaries of Anse Royale and Anse Boileau.

The dispensary at Anse Royale was well attended during the year on Mondays, Wednesdays, and Fridays by the poor; during the year there were 400 consultations.

A dispensary is held at Anse Boileau every Thursday morning; the number of consultations for the year was 114.

Further on I have attached tables showing the diseases treated at the dispensary and the number of consultations under each disease.

Vaccination.

I have nothing but praise for the vaccine lymph supplied; it nearly always took first time except when it got over four weeks here, when the lymph seems to lose vitality. It produced large typical vesicles; one case is returned as unsuccessful, but I am of opinion this child is immune, as I vaccinated it with fresh lymph, then I tried it with lymph taken direct from the arm of a healthy child, result always the same.

Successful first time	126
,, second time	19
Unsuccessful	1
Total number of vaccinations	146

Surgeon's Work in Police Cases.

During the year there were twenty-nine police cases at Anse Royale of wounds and blows, and six at Anse Boileau. The bulk of the cases were trivial, slight blows and contusions; some of the wounds were of a more serious nature that could be called dangerous to life.

On July 8th the Sub-inspector of Anse Royale reported the death of a man at Anse Louis under suspicious circumstances. Accompanied by the Sub-inspector I examined the body. I found a few slight marks on the head of no importance. From an investigation made by the Sub-inspector it was proved that the man was drunk on the evening before; he must have fallen at the place where the body was found, thus accounting for the wounds on the head. From examination of the body no apparent cause of death could be found, so a certificate was given of cardiac failure, following alcoholic poisoning.

a Senile decay: there were two people who died at the ripe age of 114 years and 100 years.
b This person was declared as 53 years of age at death. I am of opinion the age was nearer to 70.
c One of the cases of gangrene of the lungs could also be declared under tuberculosis.
d Child of a coolie immigrant at Pte. au Sel camp. The child lived 3 days. Mother refused to give it any nourishment, as it seemed to be the caste custom. Child, being a puny infant, gave up the contest, and died on the 3rd day.
e One of the cases of endocarditis was due to alcoholic excesses and exposure. I made a complete inquiry into the case.
f A *post mortem* was made in this case.

Comparative Tables of the Ages at which Death occurred during the years 1902, 1903 and 1904.

Years	1 year	Over 5	20	30	40	50	60	80	90	Over 90 years	Total and Remarks.

Medical Report on the Praslin District for the Year 1904.

By Dr. R. Laidlaw, Assistant Medical Officer.

During 1904 the health of the community has been exceedingly good, the birth-rate high, and the death-rate low.

The Leper Home and Pauper Camp have fed and ministered to the needs of their inmates as in past years; and, considering their depressing circumstances, there has been a fair amount of contentment.

Various efforts have been made to entice the inmates to engage in some form of light work, but without success. Basket-making, brush-making, and plain-stitching have been proposed to some of the more active, but only to be quickly abandoned. They seem quite unable to see that some light occupation would lessen the monotony of their life, and add to its pleasures. A little is done by one leper in the shape of a vegetable garden; and a few others engage occasionally in rock-fishing. One female pauper, said to be over a hundred years of age, finds her chief delight in ground weeding, and in cleaning in front of her little house. No other male or female pauper shows a like spirit.

In December, 1904, the inmates were the same in number as in January, 1904, viz., 9 lepers and 10 paupers.

At St. Anne and Grande Anse, Praslin, and at La Digue, the three dispensaries have given free medical help to all needy cases. The number treated during the year has been:—

243 new and 165 old cases,

as against 159 new and 143 old cases the year before.

In an appendix a table is given of the more frequent diseases treated. All grave cases requiring continual care have been sent as usual to the hospital in Mahé.

No epidemic disease appeared in the district during the year; and no case of measles (so prevalent the preceding year) has occurred. A few sporadic cases of chicken-pox appeared, but they caused no serious trouble, and its spread was limited to the household where the first case arose.

The dreaded disease of leprosy is apparently stationary. The fresh cases arising outside Round Island simply counterbalance the deaths. A family liability to the malady is usually traceable in every fresh case. Even if the last new remedy, "leprolin," fails to be a specific, the gradual extinction of the disease from general causes is very probable. Strict segregation of all existing cases would probably hasten this desirable result.

The round-worm is still a widespread plague. As many as 50 worms have been passed, in some cases, after one dose of antidote. In one case 98 worms were.

Besides wounds arising from assault, incised wounds from cutting instruments have been common. In three cases the fingers of children have required amputation, and also the finger of an adult. In this case the neglected wound had mortified.

The estimated total population of the district on January 1st, 1904, was 2,982, and during the year the deaths among them were 42 in number. During the preceding year the deaths numbered 65.

Seven of the deaths during last year were those of children under twelve months. Mistaken methods of feeding are often to blame.

One hundred and seven births occurred during the year, outnumbering the deaths by 65. The one regrettable feature is the large proportion of illegitimate births. One-third of the whole (32 out of 107) were born out of wedlock.

The vaccine imported from home has given fair results on the whole, except that received at the close of the deranged arrival of mails.

Its delay in transit then seems to have wholly destroyed its activity.

The vaccine used in December was successful in almost every case.

APPENDIX.

Nature of Cases occurring in Dispensary Practice.

Abscess.	Hordeolum.
Adenitis.	Hysteria.
Amenorrhœa.	Impetigo.
Anæmia.	Insomnia.
Amygdalitis.	Keratitis.
Anasarca.	Laryngitis.
Ascites.	Leprosy.
Asthma.	Locomotor Ataxia.
Blenorrhagia.	Marasmus.
Bright's Disease.	Metritis.
Bronchitis.	Menorrhagia.
Bruises.	Neuralgia.
Bubo.	Nephritis.
Cardiac Palpitation.	Ophthalmia.
Valvular Disease.	Oesophagitis.
Caries.	Orchitis.
Cataract.	Ovaritis.
Catarrh.	Paralysis.
Constipation.	Periostitis.
Conjunctivitis.	Pleurisy.
Cystitis.	Pruritus.
Dentition fever.	Retinitis.
Dog-bites.	Rheumatism.
Dysentery.	Senile debility.
Dysmenorrhœa.	Spinal paralysis.
Dyspepsia.	Stomatitis.
Eczema.	Syphilis.
Emonisis Menne. ?	Tic douloureux.
Epilepsy.	Tonsillitis.
Epididymitis.	Toothache.
Fever.	Tumour.
Fibroid tumour.	Ulcer.
Fractures.	Whitlow.
Gastritis.	Worms.
Goitre.	Wounds.
Gonorrhœa.	Varicella.
Hæmoptysis.	Vomiting.

Colonial Medical Reports.—No. 13.—SOMALILAND.

Medical Report of the Somaliland Protectorate for the Year 1904.

By A. J. M. POGETY, M.D.

Senior Medical Officer.

General Health of the Districts.

In two of the large districts, namely, those of Berbera and Bulhas, a severe epidemic of small-pox has occurred. This epidemic has now practically ceased.

Meteorology.

The conditions in those parts of the Protectorate which were free from the above epidemic of small-pox show a generally favourable meteorological condition, with a slight increase of rainfall. For the Province:—

In 1903 this was 1·47 inches; in 1904, 3·29 inches

Population.

The total population of the Protectorate is given at 300,000. I am of opinion that the population from which patients are drawn does not much exceed 20,000 in all, accounted for more by the native independence of character than actual distance from European-managed hospitals.

Major Operations.

Of the eighteen major operations performed at the different hospitals, I think it is particularly gratifying to note that only one death occurred. The local conditions are certainly not unfavourable, therefore, to operative procedure under ordinary aseptic precautions.

Tabulation of Diseases.

I have endeavoured to amplify this table where advisable in the paragraphs which follow it, as the classification is, of course, a wide one, and is not altogether free from cases of doubtfully correct diagnosis.

Dysentery.

Of the very large number of these cases recorded in the returns, I have been unable to meet with a single case of true dysentery during the eight months I have been in the country, and though it doubtless does occur, the cases so recorded by the hospital assistants seem to have never been more severe than a mucous colitis, and in one case was confused with hæmorrhoids.

Malarial Fever.

Intermittent fever seems alone to be of frequent occurrence. It is attended by unusually high temperatures, and shows itself to be most markedly wanting in true periodicity in character. I hope to report before long on the types of anopheles mosquitoes met with locally, certain varieties not being numerous enough to easily secure specimens, causing the delay.

It is especially worthy of note that no cases of hæmoglobinuric fever are recorded.

New Growths.

No cases of malignant new growths are recorded. The non-malignant growths were:—

(1) Papilloma of the face.
(2) Myceloma of the foot.
(3) Lipomatous tumours.

Tubercle.

Some at least of the recorded cases are open to very considerable doubt, as no microscopic examination was made. The number of cases recorded seems to be gradually increasing, however.

Digestive System.

Caries of teeth and constipation are responsible for the bulk of the digestive system diseases.

Diseases of the Skin.

The large number of ulcers shown may be taken collectively to be the usual foul spreading ulcers met with on the ankle of badly-nourished natives over most parts of Africa, and are occasioned by dirt and carelessness in attending to slight abrasions.

Parasitic Diseases.

These diseases seem to be unusually rare on the coast, at least for a tropical region.

Boils.

During portions of the year boils are met with in more or less epidemic form, chiefly during the hot season, when much fine sand is carried in the air by the wind.

Diseases Affected by Occupation.

No special race or occupation disease is noted, except that of ringworm, which is frequent among the Soudanese pearl fishers and boatmen.

The following diseases, of special interest with regard to their distribution in tropical medicine, have not been met with :—

General Diseases.

Anthrax, hydrophobia, cholera, enteric fever, dengue, cerebro-spinal fever, rheumatic fever, beri-beri, lethargy, siriasis.

Diseases of the Blood.

Filariasis (F. nocturna or F. ozzar di).
Trypanosomiasis (Glossina papalis. G. morsitans).
Eosinophalia (of Flavia of ankylostomiasis).

Diseases of Urinary System.

Bilharzia. (In this I would beg to correct Mr. Sandwich, *Practitioner*, Oct, 1904.)

Diseases recognised by examination of fæces :—

Ankylostomiasis, Tricocephalus dispar, Anguillula intestinale, oxyurus, Vermicularis tænia, sprue.

Diseases of the Skin.

Leprosy, yaws, Dermatobia noxiatus. Congo floor maggot (or the fly Auchmeromyia luteola).

Local Affections.

Liver abscess, ainhum, goitre, guinea worm, chigger (jigger), ground itch.

No. 14.—WINDWARD ISLANDS, ST. VINCENT.

Medical Report on the Windward Islands, St. Vincent, for the Year 1904.

By C. W. BRANCH, M.D.,

Medical Officer, Kingstown District.

Colony Hospital.

(1) During the year there were 697 admissions, making, with those remaining from the previous year, 748 cases treated. This is far lower than the totals for the two previous years. It is not easy to explain this difference.

On the whole the population was healthier, no doubt, during 1904-5, but there were also admissions for uncinariasis. The labourers in the neighbourhood of the town have been, perhaps, to a great extent cleared of this parasite.

From the country only exaggerated cases reach hospital.

(2) The death-rate was high compared with that of the year before—52 deaths, or 6·95 per cent. of the total cases.

We have been unlucky in getting a large proportion of moribund cases; 17 died within three days of admission.

Table I.

Died on day of admission ...	... 3
,, ,, day after admission	... 4
,, 2 days after admission	... 6
,, 3 days after admission	... 4
	17

(3) The daily average of inmates for the year was 55, compared with 65 and 66 of former years.

(4) An abstract of admissions and results is shown in Table II.

An analysis of the diseases treated is presented in Table III.

(5) There were 229 operations scored, the nature and gravity of which appear in the classification appended (Table IV.).

The rule I have always followed in counting deaths after operation is to include every case that dies before leaving hospital, if he has been operated on, without reference to the time that has elapsed or the cause of death.

Changes of Staff.

(6) In April, 1904, I was absent at the Quarantine Conference in Barbados. Dr. C. N. Durrant acted for me.

On December 14th, 1904, I went on leave of absence for three months. Dr. C. N. Durrant acted in my stead until March 14th, 1905, when I resumed.

On July 27th, 1904, Miss Rachel Paterson, the special nurse, having completed the term of her engagement, returned to England. I can hardly overrate the value of her services to the hospital, and to the poor of the Colony. The improvements brought about by her suggestions, example and teaching, are a lasting memorial of her stay in St. Vincent. With her assistance, surgery of an ambitious character was feasible; but it is the best tribute to her teaching that aseptic abdominal surgery has been done since she left, with only the native nurses to carry out the details of preparation and nursing.

It seemed for some months after Miss Paterson left as if we should not be able to repair that loss until, through the generosity of the Colonial Nursing Association, we were fortunate enough to secure the services of Miss Beatrice Empson, who arrived in the Colony on March 28th, 1905.

(7) It is most desirable that the office of special nurse should be made permanent. West Indian hospitals can, with the help of such capable women as we have had, be raised to a high standard of efficiency. It is lamentable to think of how they must degenerate if such help cannot be maintained.

There is abundance of work, and I venture to say, work of an interesting and instructive character. The poor of the Colony experience and gratefully appreciate the way in which the ladies sent to us have done that work.

It is to be hoped that a way will be found to perpetuate the arrangement, that we may not suffer by having known better things.

Statement of Expenses. (Table V.)

(8) £1,305 were provided by the estimates for the year's service. Of this £260 16s. was saved. Paying patients and police contributed £36 11s. 10d. to revenue. The total saving on the estimates was, therefore, £297 7s. 10d.

Out-patient Department.

(9) This being the first complete year since the establishment of this part of the hospital work, a report can now be made. There had formerly been no out-patients of the hospital; the ordinary district cases of Kingstown and No. 1 District were seen by the medical officers at the hospital office.

As a slight effort to grapple with the tertiary syphilis of the island, I took on myself to treat all cases that came to my notice, and give free medicine from the hospital for as long as they could be induced to continue with the treatment.

It is not necessary for these chronic cases to be seen frequently by the doctor, and it was some tax on their time to wait often for hours their turn to come in.

In 1903, therefore, I issued cards which entitled the holders to free medicine and medical attendance at the hospital. After some months' trial the scheme seemed to be working well. It was then formally submitted to His Hon. the Administrator, and he had cards printed for me. The out-patient register was opened on July 1st, 1903.

When a patient has attended about twenty times he is given a new number and card. Up to March 31st, 1905, 629 cards were issued to persons from all parts of the island. The distribution of the patients is as follows:—

From Kingstown District	243
,, No. 1 District	169
,, No. 2 ,, ...	120
,, No. 3 ,, ...	64
,, No. 4 ,, ...	33
Total	629

(10) During 1904-5, 71 old patients attended 822 times, and 228 new patients were enrolled and attended 1,620 times. There have thus been 2,442 attendances for medicine by 299 patients—an average of 8·17 times each.

While many patients have been too careless or indolent to continue with their treatment, there have been, on the other hand, a large number who have consumed a considerable weight of potassium, iodide and mercury. These have received great benefit, which they gratefully acknowledge.

Though intended for the treatment of syphilis and parasyphilis, the system has been allowed to include other chronic diseases, such as cancer and consumption.

Pauper and Leper Asylums.

(11) The appended tables sufficiently exhibit the work performed at these institutions. (Tables VI., VII., VIII., and IX.)

A constant supply of potassium iodide at the Pauper Asylum ensures the circulation of patients; so that a number are returned to independent existence outside.

(12) During the year the recurring difficulty of keeping or of disposing of violent lunatics was to some extent met by the division of two wards. There are now two larger and two smaller rooms for females.

If the asylum at Grenada cannot accommodate the St. Vincent lunatics, some steps must soon be taken to provide a suitable place for the treatment of such cases.

Colonial Medical Reports.—No. 14.—Windward Islands, St. Vincent (*continued*).

No. 15.—The Straits Settlements.

Medical Report on the Straits Settlements for the Year 1903.

By Dr. D. K. McDowell.

Principal Civil Medical Officer, Straits Settlements.

Population and Health.

(1) The following table shows the estimated population and the birth and death-rates for the years 1902 and 1903 in the several Settlements.

	Estimated Mean Population		Births		Deaths		Birth Ratio per mille		Death Ratio per mille	
	1902	1903	1902	1903	1902	1903	1902	1903	1902	1903
Singapore	235,301	240,833	4,852	5,089	12,485	11,505	20·62	21·13	53·06	47·77
Penang	129,546	130,121	2,379	2,495	5,787	4,988	18·37	19·17	44·67	38·33
Dindings	4,181	4,236	135	136	185	137	32·29	32·10	44·25	32·34
Province Wellesley	110,267	117,078	3,698	3,813	3,476	3,279	31·82	32·57	29·90	28·01
Malacca	95,924	96,276	3,457	3,976	3,037	3,332	35·50	41·30	31·66	34·61
Total	581,219	588,544	14,521	15,509	24,970	23,241	24·98	26·35	42·96	39·49

(2) A notable and satisfactory feature in the above table is that in all the Settlements excepting Malacca the birth-rate in 1903 has gone up and the death-rate has fallen. The high death-rate in Malacca the Colonial Surgeon attributes, among other causes, to the heavy infantile mortality.

(3) The death-rate for the whole Colony was 39·49 in 1903, as against 42·96 in 1902, and 39·85 in 1901, and taking this as our guide, the public health of the Colony was better than in the previous two years, but it could not be considered as good. The improvement of the rate in 1903 over that of 1902 is, however, more apparent than real, for eliminating the deaths which took place on the quarantine stations, the rates would stand at 40·21 in 1902 and 39·01 in 1903, a slight improvement only.

(4) Out of the total number of deaths registered in 1903, 3,865 were amongst infants of under one year old, against 3,631 in 1902. This high infantile mortality, which was greatest among the natives, was no doubt due to want of care and over-feeding. Another factor contributing to the high death-rate in this Colony is the large number of paupers and decrepit people who find there way here from the neighbouring countries. The Colonial Surgeon, Penang, reports that strict measures are being carried out there against the landing of such undesirable people.

(5) The subjoined table gives the number of zymotic diseases in the several Settlements in the years 1902 and 1903, and deaths therefrom, not, of course, including cases imported to the Colony.

Plague.

The three cases of plague in 1903, all of which proved fatal, took place in different parts of the town among persons who had been resident here for not less than one year. One was an Indian and two were Chinese. All three cases were verified by bacteriological examinations and in no one could the source of infection be traced.

	Plague				Cholera				Small-pox

Malacca	..	..	..	..	1	1	..	..	57	22	266	40

Colonial Medical Reports.—No. 15.—The Straits Settlements (*continued*).

CHOLERA.

There were 226 cases in Singapore with 190 deaths, but none in the Settlements. The outbreak was not so severe as that of the previous year. Five cases occurred in the Lunatic Asylum, three proving fatal.

SMALL-POX.

The cases in all the Settlements were a continuation of the previous year's outbreaks, and in Province Wellesley and Malacca far exceeded those of 1902.

Several cases where the persons responsible had failed to report occurrences of small-pox were prosecuted by the Municipality in Singapore and heavy fines imposed. In Penang the Colonial Surgeon reports that no less than twenty cases were discovered after death.

ENTERIC FEVER.

One hundred and forty-eight cases, with 47 deaths, were reported in Singapore, of which 103 were treated in hospital, with 46 deaths. One hundred and forty deaths are reported from Penang, and only three cases appear to have been admitted in the Malacca hospital—two of these died. Reliable statistics from enteric fever cannot be obtained unless the cases are admitted into hospital or attended to by qualified medical practitioners. Although all dead bodies within municipal limits are inspected after death, to diagnose a case of enteric properly after death, except by *post mortem*, is difficult.

MEASLES, &c.

A few cases of measles, dengue and chicken-pox were reported in each of the Settlements. Three cases of diphtheria were treated in hospital in Singapore.

BERI-BERI.

(6) There were 1,919 admissions into hospital with 647 deaths, against 1,901 admissions and 575 deaths in 1902. The total number of deaths from this cause registered in 1903 was 1,729, and in 1902 it was 1,607. Although these figures are not so high as that of 1901, when the number registered was over 2,000, yet they show that beri-beri still contributes a high percentage in the mortality rates.

An interesting report by Dr. Leask on the existence of beri-beri in the prison at Singapore accompanies his report on the prison sanitation.

VENEREAL DISEASES.

(7) The admissions to all the hospitals from venereal diseases for 1903 numbered 1,818, with 96 deaths. It is satisfactory to notice the appreciable decrease in these figures as compared with those of the previous two years, which were 2,341 admissions with 90 deaths, in 1901, and 3,149 admissions with 171 deaths in 1902.

Of the admissions in 1903, 1,632 were males and 186 females, of whom 152 were prostitutes.

SANITATION.

(8) The general condition of the Colony, so far as the Municipalities of Singapore, Penang, and Malacca are concerned, may be considered satisfactory. The special feature in Malacca is that no outbreak of cholera has taken place there since the Municipal water supply was established.

At Butterworth sanitation has been much improved during the year; great activity is being shown in the substitution of brick buildings for atap houses. Improvement is also reported in the other districts.

(9) All the reports from the hospitals in the Colony, excepting Butterworth, state that the quantity of water supplied was unlimited and the quality was good.

HOSPITALS AND WORK DONE.

(10) The total number of admissions into the hospitals during 1903, excluding the Lunatic Asylum, was 23,150, against 25,624 in 1902. Excepting in the Tan Tock Seng Hospital and Quarantine Station in Singapore, the Leper Asylum at Pulau Jerejak, the District Hospitals at Butterworth and Bukit Mertajam in Province Wellesley and Jasin in Malacca, the admissions into the other hospitals have decreased.

(11) The subjoined table shows the work done for the last three years.

(12) The diseases responsible for the greatest number of admissions and deaths are shown in the subjoined Tables, compared with the corresponding diseases and deaths during 1902.

POISONS.

(13) There were 126 admissions, with six deaths, as follows:—

	Admissions.	Deaths.	
Opium	14	5	
Mercury	11	—	
Carbolic acid	1	—	
Alcohol	66	—	
Ammonia	1	—	
Stramonium	11	—	
Dog-bite	14	—	(Penang)

Morphia habit ...	4	—	
Ptomaine	1	1	(Malacca)
Hydrargyri perchloride	2	—	

	Number of Patients Treated			Number of Deaths			Percentage of Deaths to Total Treated		
	Europeans	Asiatics	Total	Europeans	Asiatics	Total	Europeans	Asiatics	Total
(*a*) 1901	1,094	26,401	27,495	73	3,943	4,016	6·67	14·93	14·60
(*b*) 1902	1,159	26 515	27,674	68	4,406	4,474	5·86	16·61	16·16
(*c*) 1903	1,043	24,324	25,367	45	3,911	3,956	4·31	16·07	15·6

OPERATIONS.

(14) Eighty-nine operations were performed. There were nine deaths. This does not, however, give an idea of the amount of surgery that is done, especially at the General Hospital, Singapore, in connection with the treatment of cases classified under other headings. At the General Hospital, Singapore, alone, 200 such operations were performed.

(15) As requested by the Committee of the Cancer Research Fund, two sealed bottles were sent to the Superintendent, Victoria Embankment, London. One contained three small portions of a malignant growth removed from a patient at the General Hospital, Singapore, and the other cystic kidneys removed from a patient at the Tan Tock Seng Hospital. Notes of the cases were sent together with the respective bottles. Copies of the notes were also sent to the Colonial Office.

(16) The report on the Lunatic Asylum by Dr. Ellis shows that the recovery rate for 1903 was not so good as in the two previous years. Five cases of cholera took place among the female lunatics, three of which proved fatal. Prompt action in removing them to the Pasir Panjang ward at once stopped the epidemic. It is satisfactory to learn that beri-beri is showing signs of dying out.

With the increase in the number of patients in the asylum the industry in manufacturing cloth has also enlarged. It is a pity that there is no land available for cultivation.

(17) The health of the prisoners and police force shows an improvement in 1903 over that of 1902.

(18) There was an increase of work in the Maternity Hospital, Singapore. Nearly 50 per cent. of the inmates were natives of India. No Malay women appear to go to this hospital, but the Chinese are beginning to come to it.

No probationer passed out from this hospital in 1903.

(19) The Colonial Surgeons, Province Wellesley, both report a decrease in the number of coolies engaged in the different estates, and as a natural consequence the number of coolies treated in hospital has decreased. The general health has improved.

(20) After a great deal of correspondence for some years the Government has decided to remove the Tan Tock Seng Hospital to a more healthy site.

I.—GENERAL DISEASES.

Diseases	1902		1903

	1902		1903	
	Admissions	Deaths	Admissions	Deaths
General and local	1,521	54	1,557	56

Quarantine.

(21) The work in this department, both in Singapore and Penang, still continues to be heavy. No less than 424,940 passengers were examined on arrival, and 12,991 pilgrims on departure.

One hundred and thirty-six cases of plague were landed on the Quarantine Station at Singapore, and considering the close proximity of the town to this place and that not one case has taken place in the town from amongst the passengers landed, great credit is due to those in charge of this branch of the department for their vigilance and care in carrying on their arduous and responsible work.

Much needed improvements were carried out on St. John's Island, and the staff has been increased to cope with increased work, and so ensure greater efficiency.

Out-door Dispensaries.

(22) All the returns from the three principal dispensaries and those attached to the District Hospitals, except Butterworth, show increased work.

Eighteen thousand and twenty-nine persons were treated during the year, with an average daily visit of 150. I think that in Singapore there is room for another out-door dispensary in the Chinese part of the town; in any case, should the Government at any time take up the question of restricting unqualified private practice, the preliminary steps would be the starting of more out-door dispensaries.

Vaccination.

(23) The total number of vaccinations performed throughout the Colony during 1903 was 15,496, against 14,747 in 1902. The number of births registered in 1903 was 15,509, which shows that very few children (if any) remained unvaccinated. Of course, the number vaccinated includes adults, but these are comparatively few, and there are many children who die before being vaccinated.

The subjoined table shows the number vaccinated, with the results in the several Settlements.

These numbers do not include the vaccinatione performed at the prison or quarantine station. The number in Singapore includes 1,547 cases performed by licensed vaccinators. Although Saigon lymph was used in all the Settlements, the return shows that the best results were obtained in Singapore. This points to the conclusion that the cause of failures cannot be attributed solely to the bad quality of the lymph received sometimes. The percentage of failures was highest in Malacca, namely, 20·53. The Colonial Surgeon, Province Wellesley, attributes the failures there to carelessness of the vaccinators.

Settlement	No. of Vaccinations Performed	Result				
		Perfect	Modified	Failed	Unknown	
Singapore	2,738	2,733	..	5	..	(a)
	1,337	1,258	2	36	41	(b)

Total	15,496	12,056	1,024	1,904	512	

(a) By Government Vaccinator. (b) By Licensed Vaccinators.

Report on Principal Diseases in Singapore Prison.

By Dr. J. Leask.

Colonial Surgeon in Charge.

(1) The diseases accountable for the greatest number of admissions to hospital were:—

Beri-beri, with 169 cases, as against 415 in 1902; fevers, with 168 cases, as against 188 in 1902; diarrhœa, with 112 cases, as against 186 in 1902; dysentery, with 104 cases, as against 156 in 1902; minor injuries, with 69 cases, as against 87 in 1902; eye diseases, with 57 cases, as against 31 in 1902; dyspepsia, with 43 cases, as against 66 in 1902.

Beri-beri.

(2) One hundred and twenty-five of the total of 169 cases of beri-beri were admitted during the last quarter of the year. During the first nine months of the year there had only been 44 admissions.

(3) The number of deaths during the last quarter was 14, out of a total of 16 for the whole year.

It has been noticed in previous years that the greatest number of admissions occur in the hot months

of May, June and July, and in the last quarter of the year. (See Table A.)

(4) Heat and moisture are favourable for the proliferation of micro-organisms, and this may account for exacerbations of beri-beri at these times, the proper degree of temperature on moisture being attained then.

(5) This will not always account for those sudden changes of activity which take place at times. The disease may slowly or suddenly disappear and re-appear at varying periods in the same way, and I think a possible explanation of these changes may lie in the supply, outside the human body, of pabulum to the micro-organisms, or there may be an accumulation of excretory products of the organisms themselves. The organisms may proliferate so rapidly that they exhaust the available supply of pabulum, and become quiescent until a further supply of pabulum is again available, or a favourable environment is attained.

(6) The passage of thus weakened micro-organisms through the human intestinal tract would intensify them, therefore too much importance cannot be attached to the proper disinfection of motions.

(7) At other times it would appear that the disease had been got thoroughly under. As mentioned in my report of 1898, there was no beri-beri in the prison for twelve years from 1885 to 1897, except two outside cases.

(8) The present outbreak began in 1897, the first case being in a prisoner eighteen days after admission to prison, the second thirteen weeks, and the third six days after admission.

(9) The incubation period of beri-beri is not known, Pekelharing makes it as long as five weeks, but it would be reasonable to allow that Nos. 1 and 3 were already in the incubatory stage of the disease, and possibly No. 2 also, and it may well be granted that the disease was introduced into the prison by these men, and has now become endemic, and has been from the beginning, the cause of 1,319 admissions and 67 deaths (5·07 per cent. of deaths).

(10) Many writers have advanced the theory that beri-beri is caused by diseased rice. The experiments made by Dr. Hamilton Wright in feeding prisoners on sterilised rice has exploded this; and that the diets of the prisoners could have nothing to do with the production of beri-beri was clearly shown in 1898, when a number of prisoners suffering from beri-beri were sent over to St. John's Island from this prison.

TABLE A.

TABLE SHOWING THE INCIDENCE OF BERI-BERI IN THE DIFFERENT GRADES.

Grade	1897	1898	1899	1900	1901	1902	1903

December	17	11	26	..	32	1	65	8
Total	224	28	219	9	415	11	169	13

(11) These prisoners were fed on exactly the same food as the prisoners in the gaol. All the rations were first brought to the goal, divided there, one portion going to St. John's, the other portion being used in the gaol.

(12) The prisoners on St. John's Island made remarkably rapid recoveries, while the beri-beri cases kept on occurring at the gaol just as before.

Grades.

(13) In the upper grade 9 cases occurred, in the middle grade 37 cases, lower grade 27 cases, revenue grade 5 cases, short-sentence 88 cases, and civil prisoners 3 cases.

(14) The lower grade prisoners, whatever their labour, are always in the yards, and the middle grade prisoners in their work-sheds.

(15) With the exception of a few men, who are employed as cleaners, assistant cooks, toties, grass-cutters, the short-sentence prisoners are employed at stonebreaking and wheel, the same labour as the lower grade.

(16) It is in the men working in the stonebreaking cells and work-yards that most of the cases of beri-beri occur.

(17) Very few cases occur in prisoners employed in open-air work about the kitchens, halls, or grass-cutting.

(18) From this I would infer that the ventilation in the yards is not yet what it should be, and that more exposure to sunlight should be allowed, and I would recommend that work outside the prison should be given to those men as was done before beri-beri broke out.

Nationalities.

(19) The nationalities of those attacked were: Chinese, 155, with 13 deaths; Malays, 11, with 3 deaths; Indians, 3, no deaths.

Deaths from Beri-beri.

(20) There were 16, of whom 2 were middle grade prisoners, 6 lower grade, 7 short-sentence, and 1 civil prisoner.

(21) Owing to the decrease in the number of beri-beri cases in the first quarter, the temporary work-shed outside D Block, which had been in constant use for five years, was no longer required, and sleeping in the old civil prison was discontinued.

(22) During the last quarter, owing to the increase of cases it was found necessary to use the temporary shed again. The hospital was overcrowded, and as the sleeping accommodation at the old civil prison was no longer available, 37 cases of beri-beri were sent to Malacca.

(23) At the end of the year there were 48 cases of beri-beri remaining in hospital.

Dysentery.

(24) A very severe and intractable type prevailed. One hundred and four cases were admitted, with 13 deaths, as against 150 cases and 15 deaths in 1902. During the last quarter there were 50 admissions and 8 deaths. The *post-mortem* examinations showed the whole of the large intestine ulcerated, undermined, and in some cases gangrenous.

(25) The number of cases in the different grades were: Upper grade, 8; middle grade, 17; lower grade, 18; short-sentence grade, 53; revenue grade, 6, and civil prisoners, 2.

(36) The deaths in the different grades were: Middle grade, 5; lower grade, 1; short-sentence grade, 6, and revenue grade, 1.

(27) The nationalities of those attacked were: Europeans, 2; Indians, 6; Malays, 14; and Chinese, 82.

(28) Diarrhœa and dyspepsia have caused considerably fewer admissions than last year.

(29) Fevers have been mostly of the febricula type. No Anopheles have ever been found in the prison.

Zymotic Diseases.

(30) Enteric fever: Four cases of this disease occurred, all in Chinese; three cases in January within a few days of each other, and the last case in December. All the cases recovered.

(31) The first was revenue grade No. 23, admitted to prison on October 30th, 1902, on a three months' sentence. He was admitted to hospital on January 7th, having had fever for three days. He worked as a cleaner, and his cell was in D hall.

(32) The second case was short-sentence No. 306, admitted to prison on December 1st, 1902, on a six months' sentence. He was admitted to hospital on January 9th, having had fever for two days; his work had been stonebreaking and treadmill, and his cell was in B hall.

(33) The third case, short sentence, No. 14, was admitted to prison on November 7th, 1902, on a three months' sentence, and to hospital on January 10th, 1903, having had fever for three days; his work had been stonebreaking and treadmill, and his cell was in B hall.

(34) The fourth case was a remand prisoner who was admitted to the Civil Prison on November 23rd, 1903, and was brought to hospital on December 4th, having been ill for about a week. In this case the clinical diagnosis was confirmed by a bacteriological one.

(35) The source of infection in the first three cases was probably within, and of the fourth without the prison.

Mumps.

(36) Fifteen cases of mumps were admitted, occurring in lower grade prisoners, 13; middle grade, 1; and short-sentence grade, 1.

Dengue.

(37) Six cases were admitted.

Deaths.

(38) There were 45 deaths this year in hospital. The causes of death were: Beri-beri, 16; dysentery, 13; tuberculosis, 6; cerebral apoplexy, 3; valvular disease of the heart, 2; and general debility, cirrhosis of liver, abscess of liver, peritonitis and glaucoma, with embolism of cerebral artery, each 1.

RETURN OF DISEASES AND DEATHS, 1902-1903, AT THE

Singapore Prison.

Colonial Medical Reports.—No. 16.—TRINIDAD.

MEDICAL REPORT FOR THE YEAR 1904-5.

By Dr. JAMES A. De WOLF,

Surgeon General.

MEDICAL.

Government Medical Officers.

The usual return respecting medical officers, the nature of their employment, and the amount of leave taken by them during the year is contained in Appendix A.

The following changes occurred in the medical staff:—

Dr. T. G. D. Cooper, supernumerary surgeon at the Colonial Hospital, resigned on June, 8th 1904.

Dr. Hormasji, who was temporarily employed as assistant surgeon at the San Fernando Hospital, resigned on May 31st, 1904.

Dr. Steward, appointed as supernumerary surgeon on special terms at the Colonial Hospital, Port-of-Spain, resigned on November 14th, 1904.

Dr. W. H. Meyer, supernumerary medical officer, resigned on March 4th, 1905, on account of ill-health.

Dr. E. J. Hammond, the senior medical officer of the Service, retired on pension on July 8th, 1904, after thirty-three years of faithful and efficient service.

Dr. F. A. Rodriguez was appointed to act as subsidised medical officer of Santa Cruz, from July 1st, 1904.

Dr. K. N. A. Inniss was appointed a supernumerary medical officer on August 16th, 1904.

Dr. A. Milner, District Medical Officer of Mayaro, died on November 22nd, 1904.

Dr. Charles Howatson acted as supernumerary medical officer from December 14th, 1904, to the end of the year.

Dr. Vilain acted for short periods to replace officers on sick leave.

No appointment has been made to the vacancy in the South Naparima District, the work of which has continued to be performed by the District Medical Officers of the adjoining districts of North Naparima and Oropuche.

On September 9th, 1904, Dr. Meyer, who was temporarily in charge of the Pointe-Pierre district, was obliged to take sick leave, and from that date until the end of the year the work of the district has been performed by Dr. Boucaud, District Medical Officer, Couva, in addition to his proper duties. Owing to the serious illness of Dr. Hewlett, District Medical Officer, Cedros, and the insufficiency of the medical staff, Dr. Guiseppe, subsidised Medical Officer of the Erin-Guapo district, was on September 18th, 1904, placed in charge of the combined districts of Cedros and Erin-Guapo, and has continued to discharge these double duties up to the present time.

Surgeon-General's Office.

There was no change in the staff during the year.

Medical Attendance on the Poor.

There was a gratifying decrease in the number of patients in Port-of-Spain, the attendance being 21,810, as compared with 28,686 the previous year.

The expenditure for medical comforts issued to the destitute also shows a considerable decrease, amounting in Port-of-Spain to £198 5s. 11d., as compared with £312 5s. 10d. the previous year, and £255 13s. 10d. for the Colony, as compared with £376 10s. 3d.

PUBLIC HEALTH.

A.—Remarks on the Prevalence of Certain Diseases.

Malarial fevers were, on the whole, not so prevalent as usual, and the type of the disease was, generally speaking, mild. Several of the District Medical Officers note a greater prevalence of malaria during the dry months of the year.

Two cases of hæmoglobinuric fever, with one death, occurred in Trinidad (Cedros and Mayaro), and ten cases, with two deaths, in Tobago.

The Tobago Medical Officers refer to the insanitary conditions due to the abandonment of many sugar estates and the consequent neglect of drainage as a cause of the extensive prevalence of malaria.

Dr. Robinson, District Medical Officer, No. 4 District, again draws special attention to the necessity, in the interests of the health of the neighbourhood, of having the Betsy Hope Swamp drained.

In the Colony generally, bowel complaints were less prevalent and of less severe type than in former years.

There was an outbreak of dysentery at Siparia in March, which assumed the form of a rather severe epidemic.

This was attributed by the District Medical Officer to contamination of the drinking water. It was the subject of a special investigation, and it is hoped that a source of water supply free from contamination will be found.

There were limited epidemics of—

Influenza, at Arima in February, Guaracara in May and June, North Naparima in January and March. Sporadic cases from time to time at St. Joseph, Diego Martin and Bocas.

Whooping Cough, at Arima from December to March, Toco from May to August, Gran Couva from June to July, Guaracara in June, Cedros from September to December.

The disease was of a mild type and generally unattended by sequelæ.

Varicella.

There was a considerable prevalence in Tacarigua of varicella from April to June, and from April to March, the total number of cases amounting to 68. There were also a few sporadic cases in St. Joseph, Indian Walk and Port-of-Spain, from time to time. It is worthy of note that a large proportion of these cases occurred among adults. With regard to the nature of the disease, however, there was no doubt whatever.

Still Births.

The District Medical Officers of the several districts call attention to the large number of still births, which they attribute to the absence of trained midwives and the ignorance and incompetence of those who officiate in that capacity. The most practical remedy for this state of things would seem to be the offering of a small subsidy by the Government to induce licensed midwives to reside in certain country districts.

Yaws.

Trinidad.—The returns of cases treated in the dispensaries and hospitals are appended.

The number under treatment in the District Dispensaries at the end of the year was 204 as compared with 304 the previous year, being a decrease of 100.

The Arima Yaws Hospital was closed at the end of June.

The total number of cases remaining in hospital and dispensaries at the end of the year shows a decrease of 100.

The number of cases under treatment at the St. Augustin Yaws Hospital at the end of the year was 222.

The total number treated during the year in dispensaries and hospitals shows an increase of 137.

This showing is certainly not as encouraging as I had hoped for. It is, however, to be mainly attributed to the large number of cases brought to light in the Indian Walk district. This is a district of large area, with a scattered population and many isolated villages, and until the year under review searching has been imperfectly carried out.

Dr. C. B. Reid, District Medical Officer of Indian Walk, remarks in his report :—

"The question as to whether yaws is on the increase or not in this district is a difficult one for me to answer at present. I am inclined to think it is not. The apparent increase, as seen from the return, I put down to the excessive zeal displayed by the yaws searcher and the serious and systematic manner with which the subject has been dealt with during the year. The whole district has practically been scoured, and few, I believe, have escaped notice."

All the severe cases were sent to hospital. There is no question as to the good effect of hospital treatment in this disease. This is illustrated by the fact that, of 238 from the Indian Walk District treated in hospital 9 recurred, whereas, of 215 treated in the district 92 recurred. It is the general consensus of opinion among District Medical Officers that the type of the disease is becoming less severe.

Tobago.—At the end of the year the total number of cases remaining under treatment in the hospitals and dispensaries was 466, being an increase of 140 over the previous year. The total number of cases treated during the year was 891, as against 1,037 the previous year, being a decrease of 146. About the middle of the year there was a marked falling off in the number of cases reported. On enquiry I found that this seemed to be largely attributable to the fact that, as the cases became fewer and more scattered in the districts, the labour of searching increased, and it appeared that the one shilling allowed for each case was insufficient incentive to thorough searching. On my recommendation the fee was increased to two shillings, as paid in Trinidad, and as the result of this and the prosecution of delinquents, the number of cases reported again increased considerably.

The District Medical Officers, however, agree in the opinion that there has been a marked decrease in the prevalence of the disease.

Tuberculosis.

This disease continues to prevail extensively in the Port-of-Spain and the country districts, although the mortality for the past year shows a slight decrease. Temporary provision is being made at the Colonial Hospital for the isolation of cases suffering from tuberculosis pending the erection of suitable wards.

It is very gratifying to note that an Association has been formed in the Port-of-Spain for the prevention and treatment of tuberculosis, and that the public, as far as there has been an opportunity to judge, have shown their sympathy with the movement and have indicated a willingness to contribute to its support. Premises have been secured for the purpose of establishing a dispensary for the treatment of such cases, which it is expected will be opened shortly.

It is the aim of the Association, should sufficient support be forthcoming, at a later date to establish a sanatorium for consumptives.

B.—Conditions Affecting the Public Health.

Water Supply.—The District Medical Officers of Manzanilla, Gran Couva, Guaracara, Indian Walk, Oropuche and Erin-Guapo call special attention to the defective water supply, drinking water being generally derived from ponds and pools in the river-beds. There is no doubt that a large proportion of the ill-health prevailing, more especially in the dry season of the year, in these districts, is attributable to this cause, and it is very desirable that some provision be made by the Government, in the centres of population, for storing rain-water, as has been done in Couva, Chaguanas, Morugo and La Lune.

The progress made in installing the sewerage system in Port-of-Spain has been slow. When certain amendments have been made to the Ordinance it is

the intention of the authorities to put in force the compulsory measures therein provided.

The only places in the country districts where improvement in sanitary conditions is noted by the medical officers are at St. Joseph and Cedros, where there have been extensions of concrete drainage.

The subjoined annexures by the Assistant Medical Officer of Health are appended :—

A.—Précis of the health reports received from the District Medical Officers.

B.—Summary of Mortality in Port-of-Spain.

C.—Report of Infantile Mortality in Port-of-Spain.

INSTITUTIONS.

Colonial Hospital, Port-of-Spain.

The work of the hospital continued to be very much hampered by the insufficiency of the medical staff, owing to the resignation of Drs. Cooper and Steward, and the necessity for the employment of several of the other members to supply vacancies in the medical districts.

The sewering of the main block and three of the other wards has effected a great and much needed improvement. It is hoped that the system will be extended to the other wards at an early date.

San Fernando Hospital.

The central administration block was completed on January 31st and affords much needed accommodation.

The conversion of the old dispensary and clerk's office into private wards, as suggested by the resident surgeon, would supply a much felt want and, as pointed out by him, help to relieve the overcrowding on the male side.

The new operation room in connection with the female wards and an isolation ward have been approved, and will be constructed this year.

District Hospitals.

Couva Hospital was closed for repairs from August 8th to November 30th. A new mortuary and out-patient room were built.

Tobago Hospital.—A new building has been erected giving accommodation for the matron's quarters on the upper floor and ten almshouse inmates below. The main building has been altered internally so as to provide room for 16 male and 16 female patients. The entire accommodation of the institution by these alterations and additions will be increased from 25 to 52 beds; only 10 of the additional beds, however, will be occupied this year.

Lunatic Asylum.

The report of the medical superintendent is appended.

The number of admissions was the highest since the opening of the asylum. It is worthy of note that nearly 50 per cent. of these patients were of foreign birth.

Dr. Seccombe again calls attention to the overcrowding, there being at the end of the year 117 patients in excess of the accommodation. It is hoped that the completion of the ward at the House of Refuge for imbecile and senile cases, and an observation ward at the Colonial Hospital, will afford sensible relief.

Provision has been made also in the estimates for the erection of a portion of the new buildings required at the asylum during the current year.

The tank which received the slop water of the institution has been connected with the main sewer in St. Ann's Road, thereby remedying the nuisance formerly caused by the discharging of its overflow into the Dry River. It is much to be desired that the sewerage system should be completely installed.

Leper Asylum.

There was an increase in the number of inmates at the end of the year of 24. The appointment of a male steward and night watchman has done much to facilitate the administration and improve the discipline of the institution, and since the enclosing of the grounds there have been fewer cases of absconding.

The water supply is still very inadequate. It is hoped that this deficiency will be remedied in the near future.

The male side is becoming overcrowded, and provision will have to be made in the coming year for increased accommodation.

House of Refuge.

The number of inmates at the end of the year showed only a slight increase over the previous year.

It is satisfactory to note that a larger amount of work was done by the inmates, resulting in a profit of $220.54 to the institution.

Quarantine.

During the year the quarantine authority held four meetings.

Sixty-three vessels, with crews numbering 2,439 sailors and 1,041 passengers coming from infected ports, were dealt with under the provisions of the Ordinance.

The amount received for rent of the islands was £215 17s. 1d.

The expenditure incurred in connection with quarantine amounted to £236 1s. 8d.

The result of the Inter-Colonial Quarantine Conference which met at Barbados in April, 1904, was eminently satisfactory, regulations in accordance with modern sanitary science and preventive medicine having been unanimously agreed upon, as also a convention to be submitted for adoption by all the Colonies concerned. It is expected that Ordinances in conformity with these recommendations will shortly be enacted in the various Colonies.

Immigration.

The accompanying digest shows the prevalence, and the incidence on estates, of the chief diseases treated among indentured immigrants.

Prevalence of Disease.—During the year 22,992 cases were treated in the Estate Hospitals, as compared with 27,637 last year, showing a decrease of 4,645 cases.

Malarial fever caused the largest number of admissions to the Estate Hospitals. This disease was generally of a benign type, and occurred mainly on estates in districts (*i.e.*, Oropuche and Couva) in which the natural conditions are most favourable to the causation and spread of it.

Dysentery was somewhat more prevalent than last year. The numbers of cases for the last five years have been 642, 1,059, 948, 667, and 766.

Anæmia and ankylostomiasis shows a total of 1,933, being an increase of 206 cases over last year. As yet no practicable measures have been discovered for reducing the prevalence of this disease.

Of diseases of a communicable type there were :—

Measles	...	...	...	1 case
Influenza	...	...	...	69 ,,
Erysipelas	...	...	...	4 ,,
Tubercle	...	...	...	7 ,,
Syphilis	...	...	...	222 ,,
Yaws ...	...	...	...	10 ,,
Leprosy	...	...	...	4 ,,

Incidence of Disease.—The chief incidence was on the Couva, Oropuche, and South Naparima group of estates. Malarial fever was responsible for the greatest number of admissions to these Estates Hospitals.

———

PRECIS OF THE HEALTH REPORTS RECEIVED FROM THE DISTRICT MEDICAL OFFICERS OF THE COLONY.

By Dr. J. R. Dickson.

Assistant Medical Officer of Health.

Port-of-Spain.—The health of the town was good. Sporadic cases of enteric fever and dysentery occurred from time to time. There were two cases of diphtheria in Tranquillity. "Cases of malarial fever were not only less frequently met with, but were of a distinctly less severe type."

Diego Martin.—Apart from a few cases of catarrhal affection, simulating influenza, there was no disease of an unusual nature. A few cases of yaws came under treatment; the type of the disease was less severe than in former years.

Santa Cruz.—The health of the district has been good. Malarial fever, generally of a mild type, was the most prevalent disease. The District Medical Officer calls attention to the excessive number of still births, and attributes a large proportion of these deaths to ignorance and carelessness.

St. Joseph.—Except a few cases of varicella in the month of February, and some sporadic cases of influenza, there has been no disease of an unusual nature. Malaria and anæmia were the most prevalent diseases.

The water supply is good and ample. The drains of the town (St. Joseph) are being concreted.

Tacarigua.—The health of the district has been good. Chicken-pox was epidemic from April to June, and from January to March, a total of sixty-eight cases occurring. The disease was of a mild type. Tuberculosis continues somewhat prevalent. The district medical officer notes: "I wish to draw special attention to the condition about and around the standpipes, so filthy are they allowed to become, and . . . to remain."

Arima.—The health of the district was fairly good. Whooping cough became epidemic in December and continued to the end of March; bronchitis and pneumonia occurred as complications and sequelæ and caused many deaths. Influenza was epidemic in February; digestive diseases and convulsions (in children) were frequent complications. There were no cases of typhoid fever, and a few cases only of dysentery.

The District Medical Officer directs attention to the large number of still births and the high infantile mortality.

The water supply of Arima is ample and excellent.

Manzanilla.—The general health of the district was better than in the previous year. Malarial fever was rather prevalent during the third quarter. Many cases of influenza, and acute lung diseases, occurred in January and February. The yaws returns show a steady diminution in the number of cases of the disease. The water supply continues defective.

Mayaro.—The health of the district has been fairly good. Malarial fever of a benign type was the most prevalent disease, and occurred principally in December and January. Two cases only of yaws came under treatment, one of which was a very recent arrival from Grenada.

Toco.—The health of the district has been good. Whooping cough, of a mild type generally, was prevalent from May to August. In November and December there were several cases of pneumonia.

Chaguanas.—The health of the district was fairly good. "Malaria and anæmia were the most prevalent diseases. Ten cases of pneumonia, four of which were fatal, occurred at Union Village in the month of February.

Couva.—The health of the district has been exceptionally good. Mild cases of malarial fever occurred as usual, but there were very few cases of bowel complaint, especially dysentery.

Pointe-a-Pierre.—The health of the district was good. Malarial fever of benign type was the most prevalent disease.

Gran Couva.—The health of the district has been good. Whooping cough was prevalent in June and July. Cases of malarial fever have been fewer than in former years.

With reference to the water supply, the District Medical Officer notes: "There is a stand-pipe in the village street which is useful in the wet season, but is useless in a drought, as the supply fails in three or four days.

Guaracara.—The health of the district was fairly good. Diseases of a communicable type occurred with the following distribution:—

Dysentery in May and July.

Influenza, of mild type, in May and June, with, in many cases, pneumonia as a sequela.

Diphtheria, one case in August.

Typhoid fever in August, September, October, November, January and February—in all a total of fifteen cases.

Whooping cough in June.

Dysentery was much less prevalent.

The months of highest mortality were August, February and March.

The water supply continues defective, being obtained generally from surface wells and pools in the river-beds.

Princes Town.—The health of the district was good—one case only of enteric fever occurred during the year.

Indian Walk.—The health of the district was good. There was no epidemic prevalence of disease.

Malaria fever, of a benign type generally, was the most prevalent disease.

The month of highest mortality was August.

With regard to water supply, the District Medical Officer notes: "Artificial ponds, a few muddy rivers, and a few springs form the chief water supply."

Two concrete cisterns have been built—one at Moruga, the other at La Lune.

North Naparima.—The health of the district was good. The most prevalent diseases were anæmia, malarial fever, and, during the last quarter of the year, influenza.

Oropuche.—The health of the district showed an improvement over last year.

Malarial fever was the most prevalent disease.

The District Medical Officer remarks: "The district was remarkably free from dysentery until the last month of the year, when a rather severe epidemic broke out in Siparia," apparently traceable to the contaminated water supply. "The water is still derived chiefly from open ponds or from streamlets near the villages, and these are constantly liable to serious contamination.

Cedros.—The health of the district has been fairly good.

Malarial fever was as usual the most prevalent disease, and caused many deaths. One non-fatal case was of hæmorrhagic type.

Whooping cough, confined to Icacos, occurred during the third quarter.

Dysentery prevailed generally to a slight extent.

The District Medical Officer remarks upon the large number of still births, and the high mortality among persons not attended by the medical officer.

Under "causes and conditions affecting the public health" the District Medical Officer notes: "Concrete drainage is almost general in the streets of Beaulieu Village, which is the principal village in the district, and much has been done to improve the natural insanitary conditions of the place and the environs. The water supply is neither good nor abundant, being obtained from ponds, springs, or hills, which are liable to pollution."

Erin-Guapo.—The health of the district showed no improvement over last year. The greatest amount of sickness occurred during the fourth quarter of the year, and this was also the period of maximum mortality. There has been no improvement in the water supply, and the District Medical Officer again urges the necessity for a concrete cistern for the storage of rain-water in St. Francique, the principal village of Erin.

Tobago, Nos. 1 and 2.—The health of the district generally was good. Malarial fever of a mild type was unusually prevalent during December and January.

The District Medical Officer notes: "There were six cases of hæmoglobinuric fever, of which one ended fatally; this one being the only native of Tobago among the six cases, and the temperature in this case rising to 108·4° F. before death."

The water supply is very fair. "The natural springs which are to be found in many places have all been attended to by the Warden's Department, and afford a fair supply of good water to the various villages and settlements in the country districts."

Tobago, No. 3 District.—The health of the district was fairly good. There was no epidemic prevalence of disease.

The diseases most prevalent were endocarditis, malarial fever, intestinal worms and malnutrition.

Malarial fever, of benign type generally, was rather prevalent—an incidence attributed to the large amount of land which has gone out of cultivation.

Three cases of hæmoglobinuric fever, one of which proved fatal, occurred.

The District Medical Officer again directs attention to the hardships entailed on the inhabitants of the district by the limited accommodation of the Scarborough Hospital.

Tobago, No. 4 District.—The health of the district was good. There was no unusual prevalence of any disease. Malarial fever—of mild type—was more than usually prevalent. One case of hæmoglobinuric fever came under notice.

The District Medical Officer again refers to the large number of rodent and specific ulcers, and to the necessity for the hospital treatment of these cases. Under "conditions affecting the public health," the District Medical Officer remarks: "I would again point out that it is a matter of great regret that certain large swamps, *e.g.*, Betsy's Hope Lagoon, could not be drained as of yore, and thus ensure from its pestilential odour, and certainly its malarial breeding possibilities, the wide area adjoining. I am glad to record something in the nature of individual effort in this direction by the owner of Kendal Place Estate."

TABLE OF MONTHLY MORTALITY.

Month	Male	Female	Nos.	Rate per 1,000
April	70	61	131	26·64
May	66	52	118	24·
June	81	65	146	29·69
July	86	70	156	31·73
August	95	62	157	31·93
September	75	73	148	30·10
October	88	66	154	31·32
November	71	52	123	25·02
December	80	64	144	29·28
January	66	58	124	25·22
February	63	46	109	21·8
March	67	61	128	25·6
Total	908	730	1,638	

Summary of Mortality in Port-of-Spain for the twelve months ended March 31st, 1905.

	M.	F.	Total.
No. of Deaths of Residents	908	730 =	1,638
Death Rate	—	—	27·76
Death Rate for twelve months ended March 31st, 1904	—	—	34·2

The highest mortality occurred in August, 1904; the lowest in February, 1905.

The above Table details the monthly mortality.

The principal causes of Death were:—

	Nos.	Rate per 1,000.
All Tubercular Diseases	244	4·13
Pulmonary Tuberculosis	197	3·34
Lung Diseases (non-Tubercular) ..	87	1·47
Acute Diarrhœal Diseases	124	2· 1
Chronic Diarrhœa	7	·12
Dysentery	12	· 2
Malarial Fever	32	'54
Typhoid Fever	29	·49
Chronic Kidney Disease	73	1·24
Cardiac Disease (Organic)	66	1·12
Cerebral Hæmorrhage	2	
Whooping Cough	5	
Influenza	1	
Still Births		
Puerperal Septicæmia	5	
Leprosy	6	
Malignant Disease	22	·37
Puerperal Eclampsia	6	
Liver Abscess	3	
Croup	3	
Tropical Pemphigus	1	
Tetanus	4	
Diphtheria	1	
Erysipelas	2	

The rates are calculated for all classes of the population.

Of deaths from Pulmonary Taberculosis—19 occurred in April, 20 in September, 24 in October, 1904; and 23 in March, 1905. Of Lung Diseases (non-Tubercular), 15 occurred in May, 11 in July, and 10 in August. Of Acute Diarrhœal Diseases, 16 occurred in April and 26 in June.

Deaths from Communicable Diseases (Pulmonary Tuberculosis excepted.)

	Deaths.
Typhoid Fever	29
Whooping Cough	5
Influenza	1
Puerperal Septicæmia	5
Leprosy	6
Diphtheria	1
Erysipelas	2

REMARKS.—The months of highest mortality were July, August, and October—the maximum mortality being attained in August.

(2) Diarrhœal Diseases were most prevalent during the months of April and June.

(3) Deaths from Tubercular Diseases amounted to about one-sixth of the total deaths.

Original Communications.

IS YAWS SYPHILIS?

By ALDO CASTELLANI, M.D.
Colombo, Ceylon.

To everyone interested in tropical medicine the theory is well known according to which yaws (frambœsia, parangi, pian, &c.) is simply a form of syphilis. This theory, supported by so high an authority as J. Hutchinson, has raised much discussion. The medical men practising in those parts of the Tropics where yaws is endemic are divided into separate camps: those who believe in this theory, and those who consider yaws to be a distinct disease. Among the latter some recognise, however, that the anti-syphilitic treatment is effective also in yaws, while others affirm that mercury and potassium iodide are quite worthless.

At the suggestion of Sir Allan Perry—to whom I am greatly indebted—I have studied several cases of yaws in Ceylon, and may be permitted, therefore, to express the conclusions to which I have myself arrived in regard to the nature of the disease. I may say at once that in my opinion yaws is not syphilis. It seems to me that the study of the geographical distribution, the clinical symptoms, and the histo-pathology show clearly the two diseases to be different.

Geographical Distribution.—At the present time syphilis is practically pandemic; yaws, on the other hand, is localised to some parts of the Tropics (Ceylon, Assam, Java, West Indies, West Africa, &c.). Yaws is extremely common in Ceylon, extremely rare in India. Syphilis is frequent in both countries.

In Samoa, according to Turner, syphilis was unknown up to at least 1880, while yaws has been endemic ever since the group was discovered. In Fiji, too, up till a few years ago syphilis was not present, while yaws was almost universal. Daniels has made the interesting observation that in British Guiana yaws in late years has disappeared, while syphilis is still rampant.

Symptoms and Course.—After an incubation period varying in length, but generally not exceeding three to four weeks, characterised often by signs of malaise, rheumatoid pains, headache, irregular rises of temperature, a *primary sore*, if it may be called so, appears at the seat of inoculation, which is generally extra-genital. I have never myself seen the primary lesion in its very first stage, as all my cases were in later periods of the disease. I have very little doubt, however, about its presence. The natives are very positive about it. Moreover, in Ceylon at any rate, they are in the habit of cauterising it themselves in a primitive way, so that a white scar remains plainly visible. This scar, which is usually of rather large dimensions, in all my cases was extra-genital; in women it was very often found on one of the mammæ, in men and children on the trunk and arms.

The primary growth at the seat of inoculation is apparently quite different from the primary sore of syphilis. From the description given by natives it would seem to appear as a rather large fungoid growth, covered with a crust, not very dissimilar from the elements of the general eruption which appears later on. This large, single, projecting tubercle is called "mother yaw" or "maman pian" in French patois. By the Samoans it is called "ta'rr" or "leader" (Turner). This primary growth may remain single for several weeks and even months. It often heals before the general eruption begins.

Before the typical general eruption of yaws begins some furfuraceous, whitish, pruriginous patches appear on the trunk and limbs. These may coalesce and cover large portions of the body. Some of them may disappear, leaving the skin without lustre and rough. Others may remain for the whole course of the disease. It is on these furfuraceous patches that according to many writers the elements of the general eruption appear; in my experience, however, these may develop also on parts of the skin absolutely normal.

The general typical eruption of yaws makes its appearance in the form of papules. These are at first small, often flattened, and with the epidermis intact. They may disappear, or more often they increase in size, become moist, and are soon covered with a crust yellowish or brownish in colour, formed of desiccated secretion; if the crust is removed a raw surface will be observed throwing up coarse red or yellowish fungoid granulations secreting a thin, slightly purulent secretion which soon dries into a crust again. These papillomatous growths are of various size, and practically may be found on any part of the body; they are extremely common on the upper and lower limbs, and on the face; very rare on the scalp. They may remain of the same appearance and size for months; often after a few weeks the secretion diminishes, and a process of hyperkeratosis sets in; they become of much harder consistency, and some of them, especially on the feet, may be covered with numerous hard, verrucose-like small protuberances.

Generally within three to six months in children, and six to twelve months in adults, the yaws dry up, shrink and disappear, leaving dark hyper-pigmented spots in their site. In some cases the eruption is very persistent and appears in successive crops; in other cases large irregular ulcers may develop showing often in their centre reddish papillomatous masses which in my experience do not usually heal spontaneously.

Constitutional symptoms of severe nature are generally absent during the whole course of the disease in ordinary cases; the physical examination of the internal organs does not reveal anything abnormal; a few superficial lymphatic glands may be enlarged, but in my experience this is not a constant feature. The analysis of urine does not present anything abnormal. The stools may contain ova of various worms, but this is also a frequent occurrence in normal natives.

The Blood.—In all my cases in which the blood was examined a certain degree of anæmia, never very severe, was present. The number of red blood corpuscles varied from 3,800,000 to 4,400,000; the hæmoglobin index (Fleish) from 60 to 75. The red blood corpuscles did not show anything abnormal in their shape. On several occasions I noticed a comparatively large number of polychromatic erythrocytes staining blue instead of pink with Leishman's method.

Many of these basophile red cells were micro-erythrocytes.

The leucocytes varied from 7,000 to 12,000 per cmm. In the majority of cases an increase was noticeable in the number of the large mononuclear, even when there was no sign and no history of malaria. In almost all the cases the eosinophiles were increased, this being due probably to the presence of intestinal worms as revealed by the microscopical examination of the stools, which showed frequently ova of *Ascaris lumbricoides*, *Tricocephalus dispar*, and, in a few instances, of *Ankylostoma duodenalis*.

I attach a table giving the results of the examination of blood in four typical cases with no history of malaria, and in which no ova of ankylostomata were found in the fæces, although eggs of other worms (*Ascaris lumbricoides* and *Tricocephalus dispar*) were present.

Case	Hæmoglobin	Red Blood Cells per c.mm.	Leucocytes per c.mm.	Differential count of Leucocytes (% without fractions)				
				Polimorphonuclear	Large mononuclear	Small mononuclear	Transition forms	Eosinophiles
1. Woman ..	65	3,900,000	11,000	46	34	9	3	7
2. Boy	70	4,000,000	9,000	41	26	25	6	2
3. Girl	60	3,800,000	7,000	64	15	11	2	8
4. Girl	65	4,100,000	10,000	52	20	15	3	10

The interesting point shown by the examination of the blood is the increase in the number of the large mononuclear leucocytes. This is of frequent occurrence, though not constant. An increase in the mononuclear has been noticed also in syphilis by several writers, it is, however, very common in many diseases of protozoal origin, as shown by Manson, &c.

From the brief clinical sketch given of yaws, it will be seen that the disease presents the following principal features in contrast to syphilis: Primary sore, if it may be so-called, generally extra-genital; eruption of one type only, viz., the papule which proliferates into a papillomatous growth; extremely well-marked pruritus. Moreover, in yaws *sequelæ* comparable to tertiary syphilis or parasyphilitic conditions are absent or extremely rare, though it must be admitted that our knowledge on this point is far from being complete. It is also to be noted that yaws is not hereditary and not congenital.

Pathology.—MacLeod, in his excellent paper on the "Histo-pathology of Yaws," calls attention to the following differential points between yaws and syphilis:—

(1) The proliferative changes in the epidermis are much more marked in yaws than in syphilis. When the yaws has reached a certain stage a well-marked hyperkeratosis is noticeable which is rare in syphilis.

(2) The blood-vessels in the yaws granulomata have no tendency to thickening, nor is there any endothelial proliferation such as occurs in syphilitic gummata.

(3) The plasma cells in yaws form a more diffuse infiltration, and retain their original type better than in any other of the granulomata.

MacLeod rightly states that these differential histological details must be considered collectively, as there is no individual histological character, which exceptionally might not be present both in syphilis and yaws.

Examining films from yaws granulomata stained by Leishman's method it is interesting to note the very large number of polychromatic red blood cells of very different dimensions; some much larger than the normal erythrocytes, others very much smaller. Sometimes these polychromatic cells have a granular appearance.

The leucocytes frequently contain in their protoplasm, and sometimes also in their nuclei, roundish or oval, more or less deeply blue-stained bodies. These I believe to be probably basophile microerythrocytes engulfed by phagocytes.

Inoculation Experiments in Man and the Lower Animals.—The experiments of Paulet and Charlouis are well known. Paulet (1848) inoculated fourteen negroes with the secretion taken from yaws granulomata. All of them developed yaws, the incubation period varying from twelve to twenty days, when at the place of inoculation in ten cases the first nodule of yaws appeared, soon followed by a typical general eruption. In two cases apparently the eruption did not start from the seat of inoculation.

The more recent investigation of Charlouis (1881) is most important. He first took four cases of yaws and inoculated them under the skin at various spots with the secretion of their own yaws: in three cases at the places of inoculation typical yaws granulomata developed. Charlouis also inoculated thirty-two Chinese prisoners—who had never suffered from the disease—with crusts and scrapings of a yaws. In twenty-eight cases the disease developed, beginning always from the seat of inoculation.

Moreover, Charlouis, to a native suffering from typical yaws, inoculated syphilis. The inoculation was quite successful, a primary syphilitic sore developing, followed by all the usual types of secondary eruptions.

That yaws patients are not immune against syphilis is proved also by Powell, who describes two very interesting cases of syphilis supervening on yaws.

The lower animals, as far as we know, are refractory to yaws. In Ceylon, I tried to inoculate an anthropoid monkey, following the technique used by Metschnikoff and Roux for syphilis. The inoculation did not succeed. It would be premature, however, to come to the conclusion that the disease cannot be inoculated into monkeys. Numerous experiments on various species of monkeys are necessary.

Etiology.—Various bacteria have been described in yaws: Eijkmann found some peculiar bacilli; Pariez observed numerous micrococci; Breda described a bacillus which he called "Boubas, or Frambœsia bacillus"; Powell, in 1896, cultivated in two cases a yeast which was present in the granuloma and also between the epithelial cells.

Nicholls and Watts, in 1899, found in the granulomata a coccus which they cultivated in pure cultures. The same coccus was found once in the lymphatic glands. Inoculation into animals did not succeed.

Personal Researches.—Fourteen cases of yaws were examined by me in Ceylon. In the open sores and

General eruption.

Yaws. General eruption.

General eruption

Spirochæte of the *pallida* type.

Scar at place of primary growth.

To Illustrate Dr. ALDO CASTELLANI'S article, "Is Yaws Syphilis?"

fully developed yaws all sorts of bacteria were present, cocci, sarcinæ, bacilli. When the eruption elements are, however, in the very first stage, not moist, and with the epidermis intact, no bacteria, according to my experience, are found either microscopically or by culture methods; instead of that, rare spirochætæ may be observed.

A preliminary note on the presence of spirochætæ in cases of frambœsia was published on June 17th, 1905, in the *Journal* of the Ceylon Branch of the British Medical Association. Other cases of yaws showing spirochætæ have been communicated by me at the meeting of the British Medical Association, Leicester, July, 1905, and several more cases described in the *British Medical Journal*, November 18th, 1905.

Technique.—Films are made in the usual way from scrapings of the eruptions. It is advisable to select lesions in which a secondary pyogenic infection has not yet taken place. Giemsa stain, which I have used only lately, gives good results, but Leishman's method gives also very good results, if the staining is done according to the following instructions:—

(1) Let the alcoholic solution of Leishman act for five minutes without fixing the films previously.

(2) Mix the stain with equal or double amount of distilled water, and let it act for half an hour to several hours.

(3) Wash with distilled water and leave a few drops of it on the films as usual for half to one minute.

(4) Blot and examine with very high power.

Morphology of the Spirochætæ.—In non-ulcerated lesions, and sometimes also in open sores of yaws, there may be found an extremely delicate organism which morphologically, in the present state of our knowledge, I do not think can be distinguished from the *S. pallida* of Schaudinn. The organism takes up generally a pale reddish tint when stained by Leishman's or Giemsa's method. It is extremely thin, some individuals are, however, thicker and better stained than others, though always much thinner than any spirochæte of the *refringens* type. The extremities are often pointed, but possibly due to the manipulation of the film, forms may be met with presenting blunt extremities, or one extremity blunt and the other pointed. In a few individuals one of the extremities may present a rather large roundish or pear-shaped expansion.

The length varies from a few microns to 18 and 20 microns, and even more. The number of waves varies also, but they are generally rather numerous, uniform, and of small dimensions. Sometimes a portion of the spirochæte shows numerous narrow, uniform waves, while the rest of it has no waves at all. Sometimes, also, two spirochætæ may be attached together, or apparently twisted one on the other. Two organisms close together and nearly parallel, but united at one end as described in *Spirochæte pallida*, by Schaudinn, have been seen. On the minute structure of the parasite I have not any observation of importance, but in a few individuals I have observed a few chromatoid points here and there.

In rare cases, several preparations presented, besides the spirochætæ, some peculiar bodies, extremely rare. These bodies are generally oval or roundish, 5 to 8 microns in length and 4 to 6 in breadth. Sometimes they may have smaller or much larger dimensions.

In preparations stained by Leishman's method these bodies are stained slightly purplish or bluish, and contain chromatin. The chromatin may be collected at one point near one of the extremities, or scattered at several points. Whether these bodies have anything to do with a developmental stage of the spirochæte I cannot yet say.

Spirochætæ Found in Open Sores of Frambœsia.—The fungoid ulcerations are invaded very quickly by all sorts of germs. Besides innumerable bacteria, often spirochætæ of various kinds are present. One form is rather thick, and takes up easily the stain; it is morphologically identical with the *S. refringens* of Schaudinn.

Another form is thin, delicate, with waves varying in size and number, and with blunt extremities; I proposed for this variety the name of *S. tenuis obtusa.* A third form is also thin and delicate, but is tapering at both ends: I named it *S. tenuis acuminata.* The spirochætæ of the *pallida* type, as found in non-ulcerated lesions, may also be present.

Recapitulating, I have examined for spirochætæ altogether fourteen cases of yaws, the search being positive in eleven. In one case the spirochætæ of the *pallida* type were present also in films from an excised gland. The spirochætæ found in the non-open lesions and some of those found in open sores of yaws are, in my opinion, morphologically identical with the *S. pallida* of Schaudinn. This is also the opinion of Schaudinn himself who very kindly has examined several of my specimens. My observations have been recently confirmed by Wellman in one case and by Powell in another.

Even supposing that future investigations should confirm these observations, it will be by no means proved that syphilis and yaws are the same disease. The leprosy bacillus, the tubercle bacillus, and many other acid-fast bacteria are morphologically identical; however, leprosy is not tuberculosis. It is also practically impossible to distinguish morphologically the surra from the nagana trypanosome, but the two diseases are different.

I believe, that if future investigation will prove that yaws is a spirochæte disease, the yaws spirochæte will have to be considered to be biologically different from the spirochæte of syphilis.[1]

Treatment.—According to my experience there is no doubt that the anti-syphilitic treatment is effective also in yaws, although I do not deny at all that some cases may recover spontaneously. In any stage of yaws potassium iodide in *large doses* is much more effective than mercury. As there are authors who state that this treatment is useless, I kept four typical cases of yaws without any treatment for a certain time. One remained stationary, three got worse and worse. In one of these—a woman—for humanity's sake I had to give up the experiment after four weeks, numerous large fungoid ulcerations having developed. The symptom of which she complained the most and for which she was continuously begging for some remedy, was the unbearable pruritus. As soon as

[1] In such a case the name I suggested of *S. pertenuis* (June, 1905) *seu Pallidula* (November, 1905) might be a proper one.

potassium iodide in anti-syphilitic doses was administered this symptom decreased remarkably in intensity and finally disappeared, the eruption also soon getting better.

The potassium iodide cure doing good in yaws is considered as an argument in favour of the disease being a form of syphilis. The fallacy of this argument is shown by the fact that potassium iodide has a very beneficial effect on another disease quite different from syphilis, viz., actinomycosis.

Conclusions.—The clinical symptoms, the geographical distribution, the histo-pathology of frambœsia tropica show many points of difference from syphilis. The presence of a spirochæte of the *pallida* type in some cases is not sufficient, for the reasons already stated, to come to the conclusion that the two maladies are the same entity. I agree, therefore, with such authorities on yaws as Manson, Powell, Daniels, Jeanselme, Sambon, &c., that syphilis and yaws, though closely allied, are two different diseases.

A SIMPLE AND CHEAP ROCKER FOR LEISHMAN OR OTHER STAINS.

By P. N. GERRARD, M.D.(Dublin), D.T.M.H.(Camb.).
Krian Perak, Federated Malay States.

HAVING suffered many times and oft from the "tricks" of Lieut.-Col. Leishman's excellent stain, necessity at length drove me to make the rocker of which I enclose rough diagrams, and since the adoption of which I have had the greatest comfort and infinitely better results than before I made it. The materials used by me were as follows:—

One small piece of a deal box, say 6 in. by 5 in. by $\frac{3}{4}$ in.

Four lengths of thin bamboo.

One piece of ordinary string.

Two trouser buttons.

The shot from two cartridges, or two bullets.

Two fingers of an old white glove.

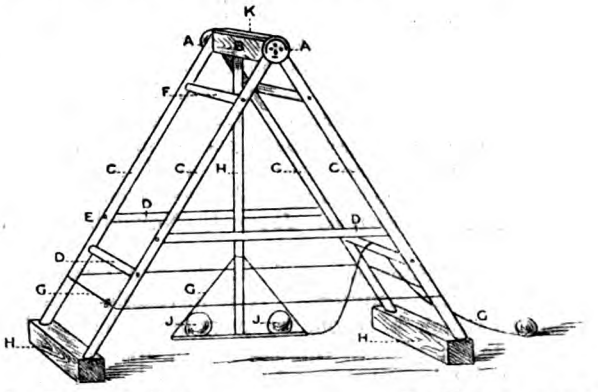
About two dozen ordinary pins and two surgical needles.

The time taken to make the machine, about an hour and a half.

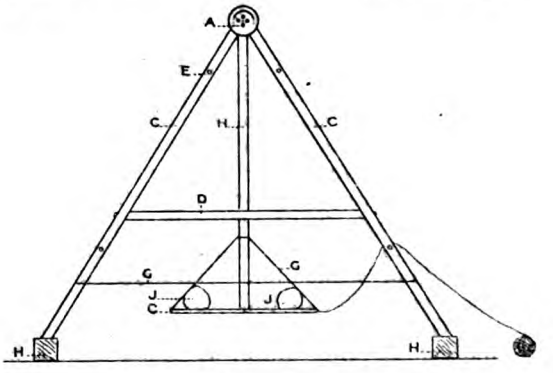
The diagrams explain the construction.

I find it works best if the stain is poured on the slide and the string then pulled, the rocking continues for about ninety minutes, depending, of course, upon the length of the supports and the weight of the shot-bags, the length in mine being 12 in., exclusive of the small square block which steadies the machine.

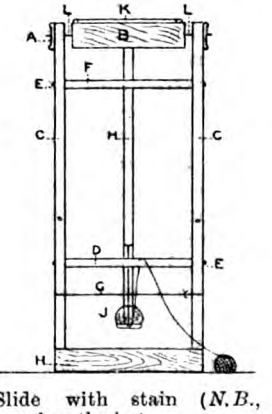
I use it on my pathology table, with two or three sheets of blotting paper under it to catch the dropping water when the stain is flushed off.

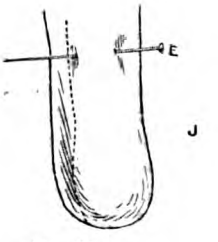


A.—Trouser button.
B.—Solid squared piece of deal.
C.—Bamboo.
D.—Bamboo spreader.
E.—Pins.
F.—Wooden spreader.
G.—String.
H.—Wood.
I.—One No. 7 split.
J.—Shot-bags.



C.—Bamboo. *J.*—Shot-bag.





K.—Slide with stain (*N.B.*, lengthwise).
L.—Surgical needle.
J.—Shot-bag.

E.—Pin.
J.—Shot-bag.

After the stain has been on about ninety minutes the rocker is almost at a standstill, and the dilution is carried out from a syphon tube (into a whisky bottle containing rain-water, filtered).

The rocking is again started and when it has slowed after the usual ninety minutes or so, another tug at the string will give another ninety minutes, and flushing can then be performed, the waste trickling down the pendulum to be absorbed by the blotting paper below. This dries in about three hours in the Tropics, and I find I have no difficulty from flooding in using the rocker three times a day, namely, for about two hours before breakfast, two hours after tiffin (one o'clock), and sometimes between 5.30 and 6.30.

I trust this may be of assistance to all who recognise the impossibility of "running" hospitals in the Tropics nowadays without a careful study of hæmic conditions.

I shall be happy to supply any further details required.

VICTORIA. MEDICAL LEGISLATION.—A Bill about to be presented to the Government of Victoria, Australia, is to the effect that no degrees will be recognised from universities other than the United Kingdom or a British possession, unless it appears to the Medical Board that such universities recognise the medical graduates of the University of Melbourne, and that Melbourne graduates are permitted to register in the country of the university. A clause is introduced prohibiting any persons but registered medical practitioners (and chemists) from dispensing medicine or rendering to any person medical or surgical aid for fee. The penalty for evading these provisions is fixed at £50.

Yellow Fever.

COLONEL WILLIAM C. GORGAS, Chief Sanitary Officer for the Canal Commission in his report for the month of August, 1905, publishes some interesting yellow fever statistics for the period from July 1st, 1904, to September 1st, 1905, a *résumé* of which is given below.

CASES OF YELLOW FEVER IN PANAMA, COLON, AND THE CANAL ZONE.

	No. of Cases	No. of Deaths	Mortality Percentage
Employees of the Canal Commission appointed from the U.S.	69	14	20·3
Employees of the Canal Commission appointed from the Isthmus ..	43	10	23·2
Employees of the Panama Railroad Company	9	2	22·2
Persons not employees of the Commission or Railroad	83	38	45·8
Transients to and from foreign ports ..	26	10	38·5

During this period 116 cases occurred in Panama, 57 cases in Colon, and 33 cases in the Canal Zone proper.

During August, 1905, there were 27 cases of yellow fever on the Isthmus.

[We are obliged to Dr. Isaac Brewer, U.S.A., for this information.—ED.]

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 ,, ,, 6/-;
200 ,, ,, 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 ,, ,, ,, 11/-;
200 ,, ,, ,, 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

JANUARY 1, 1906.

ARRANGEMENTS FOR 1906.

TO-DAY we commence the ninth volume of the Journal. The Journal of 1905 increased in bulk considerably beyond any of its predecessors, a feature which some proprietors of journals consider a subject to be congratulated upon, but which it has been our endeavour, in view of the enormous amount of literature produced at the present day, and in the desire that the JOURNAL OF TROPICAL MEDICINE shall be read from start to finish, we have attempted to avoid. No department of medical literature has increased in amount in the same proportion as that to which the JOURNAL OF TROPICAL MEDICINE is devoted, so that it is impossible to carry out the promise with which we started, that this Journal should be one as concise as possible in order to ensure its being read.

We think it may be of interest to readers to know what arrangements have been made for the future.

The Editors have had the good fortune to secure the able services of the following medical colleagues as coadjutors in the foreign literary work of the Journal:—

T. P. BEDDOES, M.B., (Cambridge), F.R.C.S. (England), for French, Spanish and Portuguese literature.

J. CAMPBELL GRAHAM, M.A., M.D., for German and Dutch literature.

J. E. NICHOLSON, Lieut.-Col. R.A.M.C. (Rtd.), for Italian, French and Spanish literature.

We have been indebted to Lieut.-Col. Nicholson and Dr. Beddoes for the past year or two for their help and co-operation in the department of foreign literature, and it is satisfactory to know that we are to continue to be benefited by their help.

Contributors sending Articles representing really Good Original Work to be Paid.

We have long felt that original articles representing really good original work sent to the JOURNAL OF TROPICAL MEDICINE should be paid for, and we have induced the proprietors to apportion a certain sum to that end. The amount at the disposal of the Editors will not allow of anything but small payments, yet we are satisfied it is a move in the right direction, and we hope our contributors will approve of the step.

The proprietors desire we should draw attention to the conditions which have always obtained in this Journal concerning reprints. A contributor of an original article is entitled to six copies of the Journal free. Should, however, reprints be desired, notice must be sent to that effect before the article is published; a small charge is made for reprints under these conditions.

The inclusion of the Colonial Medical Reports was the most important feature of the Journal during 1905. Through the kindness of the authorities of the Colonial Office we have been permitted to publish these valuable contributions, and we hope, by our doing so, the highly important and systematic records of disease from every part of the Empire lying in tropical latitudes have proved practically useful to medical practitioners in the Tropics, and will be found reliable for reference to future statistical and epidemiological writers.

SOME POINTS OF INTEREST IN TROPICAL MEDICAL WORK DURING 1905.

SLEEPING SICKNESS.

THE members of the Sleeping Sickness Commission of the Royal Society in a summary of their work state, in the No. 4 Report by E. D. W. Greig, Captain I.M.S., their conclusions:—

"(1) That the disease is at first a specific polyadenitis caused by the *Trypanosoma gambiense*.

"(2) That, in addition to enlargement of lymphatic glands, the blood shows a constant lymphocytosis at all stages of the disease.

"(3) That sleeping sickness is the last stage of this disease, and is invariably fatal. It consists, essentially, in a polyadenitis, plus signs and symptoms due to changes in the nervous system; the onset of these signs and symptoms synchronises with the entrance of the *T. gambiense* into the lymph spaces of the nervous system; this is accompanied by a rise of the mononuclear elements in the cerebro-spinal fluid.

"(4) That the resistance of both men and monkeys to the *T. gambiense*, as judged by the duration of the early stage, varies greatly, and probably a certain proportion, not yet exactly determined, acquire sufficient immunity to arrest the development of the disease at that stage.

"(5) That the action of arsenic *in vita* on the *T. gambiense* is partial. It destroys a number of the trypanosomes, and probably these act as immunising agents. Its administration in the stage of polyadenitis tends to help the natural resistance to combat the disease.

"(6) That bacterial invasion, chiefly coccal, occurs in some cases, but only in the very last days of the sleeping sickness stage, and therefore cannot determine the onset of this phase of the malady.

"(7) That, in addition to the *T. gambiense*, other varieties of trypanosoma occur in Uganda, which are pathogenic to animals.

"(8) That these trypanosomes differ entirely from *T. gambiense* in morphology and animal reactions.

" (9) That one of these trypanosomes is probably identical with *Trypanosoma brucei*. The other two differ from it, and are, provisionally, unclassed.

" (10) That these varieties of trypanosomes are conveyed from the sick to the healthy by the Uganda tsetse-fly (*G. palpalis*), and not by other biting flies (*Stomoxys*)."

It appears that the lymphatic glands of every case of sleeping sickness are enlarged, and the juice taken by puncture during life contains many active trypanosomes, and also disintegrating forms. In so-called " trypanosoma fever " the same conditions and findings obtain. It was also determined that lymphocytosis occurs in all cases of sleeping sickness. The cells met with in the cerebro-spinal fluid of the sleeping sickness cases taken during life by lumbar puncture are lymphocytes, and these are more numerous in the late stages of the disease. The presence of a diplostreptococcus in various tissues and fluids, which for some time has excited discussion as to the part it plays in sleeping sickness, seems to have been proved to have no etiological significance; but is quite a late development in the disease when it does appear, which is not always the case. All the evidence goes to show that the trypanosoma derived from the blood of early cases of sleeping sickness, and those derived from the cerebro-spinal fluid of advanced cases of the disease are one and the same, namely, the *T. gambiense*.

The tsetse-fly, the *Glossina palpalis*, seems to be the medium of transmission; and this fly, when infected, can communicate the disease to monkeys as well as to men. Trypanosomes occur in animals such as oxen, ponies, camels, dogs and mules, in the area in which the Commission was at work; but it was impossible on morphological grounds alone to arrive at a final conclusion as to the identity or otherwise of the various " strains " met with in different animals, but there can be no doubt that the *T. gambiense* differs morphologically from the animal varieties. By inoculation experiments, however, there would appear to be a marked distinction in the behaviour of the several trypanosomes met with in animals.

Lieutenants A. C. H. Gray and F. M. G. Tulloch report several observations made on tsetse-flies. They proved that the *T. gambiense* multiplies in the alimentary canal of the *G. palpalis*, and that the trypanosomes undergo morphological change in the fly. Trypanosomes taken from the intestine of the fly did not infect monkeys, but the salivary glands of the fly were seen to be occupied by trypanosomes from the intestines of the fly.

Of noted lesions in sleeping sickness the only one which seems to have been recently added is a petechial hæmorrhage in the mucous membrane of the stomach.

As regards treatment, arsenic—as sodium arseniate, as Fowler's solution, or the combination of the former with trypanroth or atoxyl, seem the only drugs which have so far given even partially beneficial results.

Malaria.

Of the several forms of prophylaxis, quinine, mosquito netting and destruction of mosquito breeding grounds, each has its advocates. The Italian Commission for the study of malaria found quinine most effective in preventing relapses of attacks of fever and in restoring the patients to health. The members of the Commission found 6 grains to adults daily, and 3 grains to children, were efficacious in preventing new infections and in preventing relapses of illness.

The objection to quinine taking is the difficulty of getting patients or persons exposed to malaria to continue using the drug, except under the strictest supervision. The same may be said of protection by mosquito netting; apathy on the part of the persons exposed to malaria is the great drawback to the complete success of mechanical protection from mosquitoes; but where supervision was possible, as in the case of the Corsican Anti-malarial League, mosquito netting proved highly, in fact completely, efficacious. Destruction of Anopheles' breeding grounds as a prophylactic agent did not find favour to any great extent in Italy, owing to the difficulty of draining the large swampy areas where mosquitoes breed. In several parts, however, this mode of exterminating malaria has given excellent results,

one of the best, perhaps, being that obtained at Klang and Port Swettenham, in the Malay States, by Dr. Malcolm Watson. In a district where eradication seemed at first sight well-nigh impossible, Dr. Watson practically exterminated malaria by systematic drainage of mosquito breeding places, and by clearing the immediate neighbourhood of shrubs and secondary jungle-growth. At Port Swettenham, during the years 1901-02-03-04, the first-mentioned year being previous to anti-malarial measures, the cases of malaria numbered 188, 70, 21 and 4.

In both Klang and Port Swettenham, malaria, as a fatal disease, was reduced to *nil*, and as a factor in illness wholly insignificant. Major Ross's work at Ismailia in the same direction gave, and continues to give, most encouraging results. In 1901, before anti-malarial measures were tried in Ismailia, there were 1,990 cases of malarial fever in the town; in 1903 and 1904 the fever cases fell to 214 and 90 respectively. It would seem, therefore, that by all methods of malaria prophylaxis—quinine taking, netting and drainage—malaria may be thwarted, and a combination of two or all of these methods affords proof that malaria is a preventible disease.

Malta Fever.

During the year 1905 no branch of medical scientific enquiry has borne better fruit than the investigation of the etiology of Malta fever by the Mediterranean Fever Commission. The Commission was formed in the early part of 1904, and in June of that year commenced regular investigations. The members of the Commission were Colonel Bruce, F.R.S., Major Horrocks, Staff-Surgeon Shaw, Dr. Zammit of Malta, and Dr. Johnstone of the Local Government Board.

The First Report by Major Horrocks was devoted to a study of the duration of life of the *Micrococcus melitensis* outside the human body. His conclusions were :—

(1) The *M. melitensis* is able to live for six days in a urine which has become alkaline from the presence of ammonia.

(2) The *M. melitensis* survives for sixteen days when spread in a thin layer on a glass cover-slip.

(3) The *M. melitensis* survives for sixty-nine days when planted in a dry sterilised manured soil.

(4) In dry sterilised sand the duration of life of the *M. melitensis* appears to be only twenty days.

(5) In a sterilised manured soil saturated with water the *M. melitensis* appears to survive for only seven days.

(6) The *M. melitensis* is able to live for eighty days on dry fabrics, such as blanket, khaki serge, and khaki cotton.

(7) The *M. melitensis* appears to live for a comparatively short time in sterilised tap-water. It was only recovered in pure culture six days after being planted out, though from the result of Experiment VIII. it appears possible that the duration of life may extend to three weeks.

Major Horrocks' Second Report consisted of "Further Studies on the Saprophytic Existence of *Micrococcus melitensis*," published September, 1904. His conclusions were :—

(1) The *M. melitensis* retains its vitality in sterilised tap-water for thirty-seven days.

(2) In a Maltese soil, allowed to dry naturally, the *M. melitensis* survives for forty-three days; and in one thoroughly dried immediately after inoculation it survives for twenty-one days.

(3) The *M. melitensis* survives for seventy-two days in a damp soil.

(4) Exposure to the sun for a few hours kills the *M. melitensis*.

(5) The *M. melitensis* survives for twenty-five days in sterilised sea-water.

The Third Report, on "The Recovery of the *Micrococcus melitensis* from the Urine, Fæces, and Sweat of Patients Suffering from Mediterranean Fever," is by Major Horrocks, in conjunction with Captain Kennedy. Up to September, 1904, the *M. melitensis* had been isolated thirty-nine times from the urine of thirteen different patients. The micrococcus was isolated not earlier than the fifteenth day in Malta fever and not later than the eighty-second day of the disease. The examination of fæces for recovery of the coccus proved negative, although as many as 1,026 plates were made from eighty-six stools. Major Horrocks remarks that many of the streptococci occurring in stools bear a superficial resemblance to the *M. melitensis*. From the sweat the *M. melitensis* had not been isolated at the time of the Report (September, 1904); the infection of bacteria-free sweat from Malta fever patients did not give the characteristic agglutinins in the blood of monkeys experimented upon; but in one experi-

ment by Staff-Surgeon Shaw, from the ordinary sweat (bacteria-bearing) of a Malta fever patient an agglutinative reaction was obtained. Experiments made to ascertain the presence of *M. melitensis* in the expired air of Malta fever patients, all proved negative; nor could monkeys be infected by the injection of broth infected by the expired air of Malta fever patients.

It has often been stated that Malta fever was caught from the polluted sea-water in the harbour of Malta, but experiment proved that the *M. melitensis* could not be detected in the sea-water of the harbour.

In the Fourth Report of the Mediterranean Commission, Major Horrocks gives details of "Experiments of the Mode of Conveyance of the *Micrococcus melitensis* to Healthy Animals." By experiments on monkeys it was shown that the inhalation or ingestion of infected dust will give rise to Malta fever in monkeys; and the ingestion of infected food (milk) proved positive, but whether the organism was absorbed by the stomach or by the mouth or throat was not determined.

The infection of healthy monkeys by contact with infected monkeys is probably through the urine excreted and not by bodily contact. The experiments made with the mosquito—*Stegomyia fasciata*—to test the possibility of the mosquito transmitting the disease proved negative in Major Horrocks's hands, although Dr. Zammit reported several cases that seemed to point to the possibility of the mosquito being the agent of transmission.

In Report Five, by Staff-Surgeon R. T. Gilmour, is given a "Description of a Method of Cultivating the *Micrococcus melitensis* from Small Quantities of Peripheral Blood and Inoculation Experiments with the Micro-organisms Isolated."

In quantities of so small amount as 1·0 cc. withdrawn from a vein of a Malta fever patient, and of this quantity 0·1 cc. in broth medium of which but 10 cc. was injected, a positive result was obtained.

Report Six, by Dr. T. Zammit, on "Isolation of the *Micrococcus melitensis* from the Blood," contains the technique to be observed in drawing blood from patients suffering from Malta fever, and the laboratory methods followed for cultivation.

Report Seven, by Staff-Surgeon E. A. Shaw, contains an "Interim Report of Experimental Work in the Investigation of Mediterranean Fever dealing with Blood, Skin, Sweat, Inoculations, Agglutinating Serum, and various Inoculations in Different Animals."

Shaw's conclusions are: (1) *M. melitensis* exists in the blood of patients in relatively very small amount, the smallest quantity of blood in which it has been found, $\frac{1}{256}$ cc., is practically the equivalent of 4 c.mm. This small amount of bacilli in the blood is interesting when the question of transmission of infection by mosquitoes is considered. (2) No definite relation can be established between any given stage of the disease and the presence of *M. melitensis* in the blood. (3) There is some indication of a diurnal variation in its presence in the blood. (4) No relation can be established between the agglutinating power of a patient's blood for *M. melitensis* and the amount of the latter present in the blood. (5) *M. melitensis* does not pass through Chamberland, F., nor Berkefeld filters, IV., V., or VI.

The most important practical point determined by the Commission was the discovery by Dr. Zammit, in June, 1905, that the goats in Malta are infected by the *M. melitensis*, that the coccus can be isolated from the milk of infected goats, and that the urine of these animals contains the specific organism. As the milk supply in Malta is chiefly derived from the goat, it is readily understood how important this discovery is. The udders of the goats are usually very large, actually touching the ground, and it is plain that the udder may become contaminated by the urine-polluted soil, so that both by mechanical means and by the secretion of milk itself the milk supply may be contaminated.

The whole constitutes a fine piece of scientific work, and the members of the Commission are to be congratulated on their work, which promises to be eminently successful in staying the ravages of this scourge in Malta. The reports received from time to time that Malta fever has been met with in places other than Malta, and perhaps Gibraltar, have to be received with some hesitation, for except perhaps the reports from Orange River Colony, in but few cases have we any authority for pronouncing the disease to be Malta fever, except from clinical evidence alone.

Beri-beri.

Next in importance to the work accomplished in Malta fever during 1905 is perhaps that of Dr. Hamilton Wright in connection with beri-beri. Dr. Wright may not have completely proved his point, but his conclusions have been arrived at after prolonged and careful study and investigation, and if he has done no more than to direct our attention into other channels of study in elucidating this mysterious disease he has contributed towards widening the field

of investigation. But Dr. Wright would seem to have done more than that, for he has by clinical and pathological demonstrations succeeded in presenting to us beri-beri in a new aspect and on a convincingly clear scientific basis. Dr. Wright's observations and conclusions are summarised as follows:—

That beri-beri is an acute or subacute infectious disease of short incubation period. That it is due to a specific micro-organism not yet isolated. That this specific organism is not one whose special habitat is a particular food, such as rice or fish, but one that may, nevertheless, be ingested with any food or drink accidentally contaminated. That this organism, having gained entrance to the alimentary canal, multiplies in the contents and mucosa of the stomach and small gut, but chiefly in the contents and mucosa of the pylorus and duodenum. That it there elaborates an extracellular toxin, which, being immediately absorbed, poisons the peripheral terminations of, first, the vagi to the stomach and heart, and then other efferent, afferent, and autonomic neurones to different extents and degrees, thus giving rise to groups of symptoms which may be broadly classified as acute pernicious beri-beri, acute, and subacute beri-beri. That these cases run a definite course of about five or six weeks, and on the elimination of the causal organism and its toxin the poisoned neurones recover and the patient becomes whole again, or that the poisoned neurones only partially recover, and there develops in those of them which do not a true degeneration which migrates centralwards. For this persistent atrophy, and the various paralyses, atrophic disturbances, and œdema which result, Wright has proposed the term "beri-beric residual paralysis."

This view of the clinical history of beri-beri points to a gastro-duodenitis as the primary local lesion in the complaint, and is supported by actual clinical observations of patients. The paralysis is a late development or even a sequela of the disease: as in diphtheria paralysis supervenes after the acute signs and symptoms have subsided, as in plague the bubo is subsequent to gastro-intestinal lesions, so in beri-beri we find an alimentary preceding the neural and other evidences of the disease.

The etiology of the gastro-duodenitis has not yet been worked out, but Dr. Wright suggests a bacillary origin, and that it is by way of the fæces that the infecting organism or material escapes from the body. Acting on this grounded belief he applied it to the treatment of the disease in a gaol at Kuala Lumpor, and was successful in practically eradicating the disease from amongst the prisoners in the gaol, which for many years had been subjected to virulent and persistent outbreaks of beri-beri.

Plague.

There is little to record concerning plague, except that it continues to prevail in the several haunts we have associated with the disease for several years. The persistency of plague when once it has established itself in a town or district is characteristic of the disease, as it has been known from early times. This fact alone, in addition to the actual mortality it entails, is sufficient to explain the dread of its appearance and the extraordinary precautions taken to prevent its inroads.

India remains the chief centre of the disease in the world at present, and except in China, no other country could have withstood the mortality which prevails there and continued to play its part in the economy of nations.

During the first six months of 1905 no fewer than 878,602 persons died of plague in India. This is the largest mortality for any period of six months yet recorded, for it is 151,971 in excess of the corresponding period of 1904, which up to 1905 presented the highest death-rate since plague appeared in India.

During the months August to November, 1905, the mortality from plague has been much reduced in India, so that possibly the death-rate for the year may be under one million, and if that proves to be true the total for 1905 will be under that of 1904, when the deaths from the disease numbered 1,034,787.

The diminution may actually prove that the virulence of the disease is abating, or it may only be a wave of subsidence with which we are familiar in the history of the disease.

Inoculation is making considerable, if not wholly satisfactory, headway in India, but more is being done in this direction than is generally known. Certain it is that inoculation affords marked protection against plague, and also considerably diminishes the case mortality of those attacked.

Haffkine's method of inoculation is the one at present followed, and there seems every reason to consider it the best. The report of Major E. Wilkinson, I.M.S., founded on work done during 1902-03 is satisfactory evidence of protection. In a community of 827,427 persons 639,630 were not inoculated, 187,797 were inoculated; of the former 29,723 died of plague, whilst

among the latter there were only 814 deaths from the disease. Had the 187,797 not been inoculated the presumed number of deaths would have been 8,680, in place of the 814 which actually did occur. But by the inoculation it would appear that some 7,866 lives, or stated in percentages 90·62 per cent., were saved by the inoculation.

A report from Aden by Mr. E. S. Winter also confirms the efficacy of inoculation, and from several parts of India we have similar accounts. Stated broadly, it appears that inoculation affords well-nigh an eightfold degree of immunity ; and when plague has developed amongst an inoculated community, less than half the number of deaths occur than amongst those not inoculated.

We are indebted to W. J. Simpson, Hunter and Bell, in Hong Kong, for a more clear clinical history of plague than any yet advanced. These observers showed that plague was in most instances a disease set up by infection by way of the alimentary canal, and that the bubo is a rather late development in the illness. Gastric and intestinal lesions precede the lymphatic gland enlargements. They at the same time admit the possibility of a direct pneumonic infection. This view of plague was a great stimulus to further investigation and afforded a key to prophylaxis.

The vexed question of the relation of plague in rats to plague in man is not yet settled. There can be no doubt that men and rats suffer in common from the disease, but whether they are both infected by some common agent or whether they stand to each other as cause and effect is not determined. The suggestion that the black and brown rats play different parts in the disease was first mentioned by Cantlie in 1897, and the idea has been elaborated since then. The black rat —the *Mus rattus*—is more a household pest than is the *Mus decumanus*, or brown (Norwegian) rat, which lives chiefly in drains and outhouses ; and it is considered possible that the geographical distribution of these rats aids in determining the geographical distribution of plague in man.

Yellow Fever.

Around the Gulf of Mexico yellow fever prevailed during July, August, and September of 1905, and even in October and during November cases of the disease were reported. New Orleans seemed to be the chief centre of the outbreak. Cases were first notified in New Orleans in July and up to the end of the second week in November, when the disease seemed to have well-nigh wholly subsided, some 3,400 persons were attacked by yellow fever. The deaths from the disease numbered 451, a mortality rate of 13·20 per cent. only. The only other town on the northern littoral of the Gulf of Mexico where yellow fever seemed rife was at Pensacola, a town situated in Florida, close to the Alabama frontier, and only a short distance by sea from New Orleans. In Pensacola 560 cases and 80 deaths were reported, again furnishing a remarkably low death-rate, some 14·28 per cent. only. It is a curious turning of the tables that Havana, the home of yellow fever in Cuba for some 150 years, and the centre from which the disease formerly spread to the Gulf of Mexico ports, should during the recent outbreak have been taking rigid quarantine steps against infection from New Orleans and other ports. Since the determined suppression of yellow fever in Havana some two or three years ago the city has been practically free from the disease, and the few cases that occurred during 1905 were described as imported cases merely.

Yellow fever was stamped out in Havana by the practical application of the belief that the *Stegomyia fasciata* mosquito is the means by which the disease is transmitted. This plan of yellow fever prophylaxis was practised also in New Orleans and elsewhere, but not until the disease had got a fairly firm hold upon the communities.

The treatment of the disease has not advanced beyond treatment by "general principles." An initial purge, a vapour bath, a mustard bath to the feet, stimulants, alcohol, strychnine and caffeine when indicated, diuretics and hot wet packs for suppression of urine, constitute the sum and substance of yellow fever treatment at present.

Tick Fever.

Excellent work in the elucidation of tick fever has been done by J. L. Todd, by the late T. Everett Dutton, and by Drs. Ross and Milne in the Congo Free State. A spirochæte has been demonstrated to be the specific agent in the causation of human tick fever. The *Ornithodorus moubata* (Murray) is the tick by which the spirochæte is transmitted from animal to animal, and monkeys also have been infected experimentally by allowing ticks to bite them.

Human tick disease was described by Livingstone. He first noticed the disease in Portuguese South Africa, and he also mentions being annoyed by the tick whilst

staying at Nyangwé in 1871. The natives in the tick-infected districts have always declared that the bite of the animal caused illness, but it was not until 1904 that their contention was absolutely proved by scientific investigation.

The Course of the Disease.

Incubation Period.—One week.

Invasion, Signs, and Symptoms.—The onset is sudden, but a distinct rigor has not been noted. The patient is suddenly prostrated and complains of head-ache, bone-ache, and back-ache. Vomiting generally obtains at the commencement of illness. Diarrhœa is fairly constant, but constipation may occur. There are usually three or four attacks of fever, each attack lasts from three to four days, with marked relapses extending from a period of five to as many as nineteen days. The temperature during the feverish attacks may rise towards the evening to as high as 104° F. or to over 105° F. The attacks usually end in a marked perspiration. The most notable feature of the disease is the extreme prostration which prevails during the febrile attack and the sudden recovery of spirits and the feeling of fitness as soon as the temperature falls to normal. The spleen is sometimes enlarged. Herpes, epistaxis and hiccough have been recorded during the attacks.

The spirochætæ, when numerous, can be readily seen in fresh preparations of blood as rapidly moving spiral threads. When the parasites are scanty in number the best method of demonstrating their presence is by dehæmoglobinising a thick blood film and staining by some modification of Romanowsky's method, or a weak solution of carbol-fuchsin.

The distribution of the human tick in the Congo Free State is interesting. Livingstone says before the Arabs came to the country bugs were unknown, and that wherever the Arab traders went the bugs were met with. This holds good at the present day, for tick fever is confined to the commercial highways; these are the old caravan routes and the rivers. It is probable, however, that ticks reached the Congo Free State from the east, carried by the Arabs, and from the Portuguese territory to the south.

The conclusions arrived at by Drs. Dutton and Todd are:—

(1) Tick fever is clinically identical with relapsing fever, and has for pathogenic agent a spirochæte.

(2) The spirochæte is probably *Spirochæte obermeieri.*

(3) The tick *Ornithodoros moubata* can transmit the spirochæte from animal to animal.

(4) The transmission is not merely mechanical, but some developmental process is carried on in the tick.

(5) A considerable degree of immunity or tolerance to the spirochæte can probably be acquired.

J. C.

LIVINGSTONE COLLEGE.

The annual report of Livingstone College for the year 1905 is one which must serve to encourage all those engaged in furthering the admirable work which is being so ably conducted there. By the acquisition of a neighbouring plot of land, through the generosity of Mr. Robert Barclay, the College has been freed of the possibility of being overlooked by cheap dwellings, which were contemplated being built close by. The medical education given by the Principal, Dr. C. F. Harford, and other members of the staff has proved of pronounced benefit to missionaries proceeding to up-country districts in tropical countries. The marvel is that the number of students at the College have been so few; for one cannot conceive missionary societies sending men or women to outlying parts of the world, where no medical men are available for advice, without their having previously availed themselves of the opportunities afforded by the Livingstone College, whereby not only the health of the missionaries themselves may be better maintained, but also the physical welfare of the natives who come to them for spiritual instruction.

That the College is fulfilling its functions in a circumspect manner cannot be better gathered than from the statement made by Dr. Donald MacAlister, President of the General Medical Council, at the lecture on "Risks to Health in the Tropics, their Relation to Imperial Expansion and Missionary Enterprise," given at Cambridge on November 22nd, 1905, by Dr. C. F. Harford. Dr. MacAlister said:—

"If you like to quote me you may do so as saying that I have watched with interest, and perhaps some solicitude, the development of Livingstone College. I had doubts lest its initial purpose of giving to missionaries about to settle in tropical countries such lessons in the elements of hygiene and of medical and surgical first aid should be diverted to that of enabling imperfectly trained or unqualified men to pose as doctors in foreign parts. If that doubt had been confirmed, I, as official guardian of the Medical Register, would not be there that night; but I had satisfied myself that this was neither the purpose nor the effect of the training afforded at Livingstone College. I was sure that so long as a medical man so excellently qualified by experience, knowledge and prudence as Dr. Harford was responsible for the instruction given and the policy pursued, nothing but good could result to missionaries and their flocks from the fact that they had passed through the College."

We propose to deal more fully with the report in our next issue.

To the Editors of the "Journal of Tropical Medicine."

Sirs,—I enclose an illustration of an instrument invented by myself, though not patented, for the examination of the throat by day or by night.

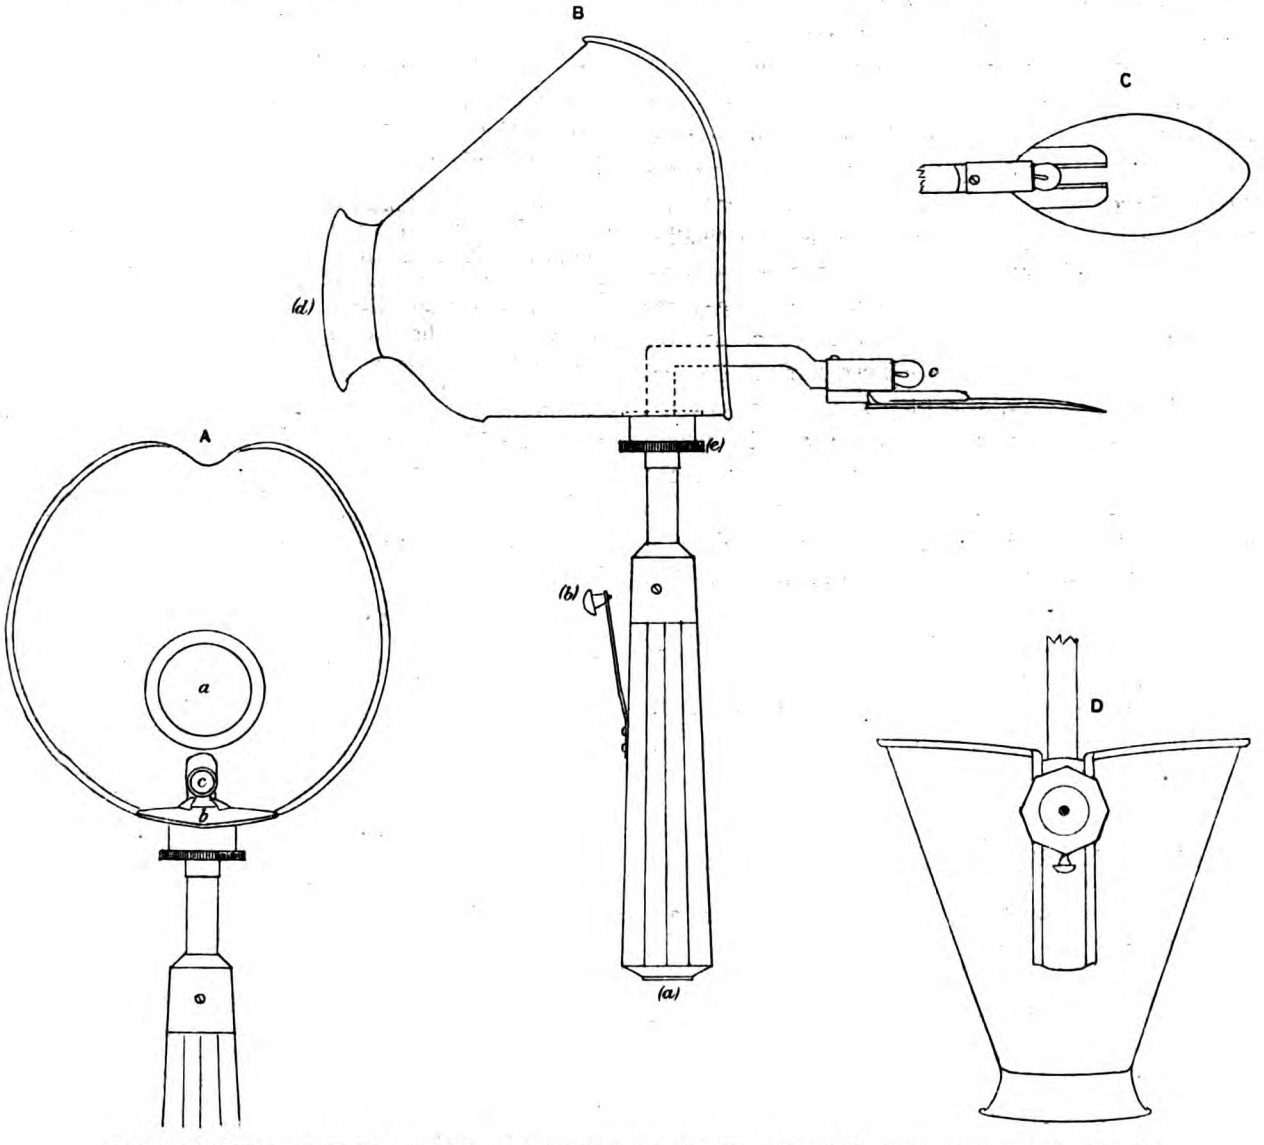
A gives the front view of the instrument, showing at (*a*) an opening of a circular form, fitted with a piece of plain glass, through which the fauces and palate, the mouth, pharynx, and upper part of the œsophagus, as well as the epiglottis and larynx with vocal cords, may be clearly seen by day or by night. In the latter case an electric lamp at (*c*) illuminates these parts, while (*b*) depresses the tongue and so gives the surgeon a good view of the parts behind and below the root of the tongue. It protects the surgeon or physician while examining cases of infectious throats.

B gives a side view of the instrument.

C the tongue depressor detached, and can be lengthened or shortened.

D the face-piece also detached.

At *B* the detached parts, *C* and *D*, are to be seen connected and ready for use. At this point (*a*) is attached the wires of the battery which pass through an opening at the bottom of the stem when required for use; at (*b*) you press the button on to the stem and in contact with the latter a powerful little electric light is emitted at (*c*); while through the glass opening at (*d*) you view the parts of the patient's mouth, throat, and windpipe. The face-piece can be either fixed firmly at the point (*e*) by the revolving disc, or it can be moved freely to any direction you desire to fix your examination upon. If you desire to obtain a clear view of the larynx and vocal cords you depress the stem, which also causes the tongue to be depressed by the tongue depressor, *C*. To obtain a magnified view of the parts you can attach either a magnifying glass at (*d*), or the binocular glasses properly focussed.



Invented by Major G. H. Fink, I.M.S., M.R.C.S.(Eng.), L.S.A.(Lond.), and the instrument made for him by Messrs. Down Bros., London.

Yours, &c.,

G. H. Fink.

Notes and News.

THE Director of the Wellcome Physiological Research Laboratories desires to notify the medical profession that in consequence of the increasing demands upon the space available at these Laboratories in connection with physiological and bacteriological research and the production of therapeutic serums, *clinical diagnosis work in this Institution will be discontinued on and after December 11th*, 1905.

The clinical diagnosis work will be transferred to—Dr. E. C. Bousfield, The Camberwell Research Laboratory, 363, Old Kent Road, London, S.E.

MEDICAL CONGRESS AT LISBON, 1906.

Thursday, April 19, to Thursday, April 26.

THE Orient-Pacific Line beg to notify that they propose sending their fine twin-screw s.s. *Ophir*, 6,814 tons register, 10,000 horse-power, to Lisbon, for this Congress.

The fare for the seventeen days' cruise (exclusive of shore excursions) will be from £15 15s. upwards, according to the position of cabin occupied.

Plan of the steamer and further particulars will be sent on application.

Managers: F. Green and Co., Anderson, Anderson and Co. Head Office: Fenchurch Avenue, London. For passage apply to the latter firm at 5, Fenchurch Avenue, E.C., or to West End branch office, 28, Cockspur Street, S.W.

PROGRAMME OF CRUISE BY THE "OPHIR."

Thursday, April 12th, 2 p.m., leave Tilbury.

Friday morning, call at Cherbourg to embark Continental passengers.

Sunday, 15th, at Vigo.

Tuesday, 17th, at Tangier and Gibraltar.

The principal places of interest ashore will be visited.

Wednesday, 18th, 6 p.m., arrive Lisbon. During the stay of six days at Lisbon various excursions will be made, including visits to Madrid, Toledo, and the Escurial.

Tuesday, 24th, 6 p.m., leave Lisbon. Passengers who wish can leave at 4 p.m. next day, Wednesday, and rejoin the *Ophir* by train at Leixoes.

Wednesday, 25th, at Leixoes (for Oporto). The day will be spent ashore visiting the principal sights.

Saturday, 28th, call at Cherbourg to land Continental passengers.

Sunday, April 29th, 8 a.m., arrive back at Tilbury.

Plague.

India.—During the weeks ended November 25th, and December 2nd, the deaths from plague numbered 2,836 and 2,890.

South Africa.—No case of plague during the weeks ended November 25th and December 2nd and 9th in Cape Colony.

Mauritius.—During weeks ended December 14th, 21st, and 28th, fresh cases of plague numbered 8, 5, and 2; deaths from the disease, 7, 3, and 2.

Hong Kong.—During the week ended December 23rd, fresh cases, 3; deaths from the disease, 3.

New Drugs.

THE pharmaceutical preparations of Messrs. P. Beiersdorf & Co., of Hamburg, have long been renowned for their purity and excellence. The readers of the JOURNAL OF TROPICAL MEDICINE will be interested to learn that this firm achieved great distinction at the "Exposition Universelle," held at Liège in 1905, they having gained the highest possible award, the Grand Prix, for their pharmaceutical specialities.

We congratulate Messrs. P. Beiersdorf & Co. on this signal triumph, which is the more significant, inasmuch as their products were the *only* ones of German manufacture to gain the highest award, the Grand Prix, at the Liège Exhibition.

"ERNUTIN." A new product presenting the active therapeutic principle of Ergot.

"Ernutin" is issued in hermetically sealed phials, and being sterile is eminently suitable for hypodermic or intramuscular injection. When it is desired to obtain an immediate effect, as in *post-partum* hæmorrhage, intramuscular injection is to be preferred.

As "Ernutin" is a very potent preparation, its administration must be carefully guarded, and the dosage regulated accordingly. It is suggested that the initial dose be five minims, and that any subsequent dose required should depend upon the ascertained reaction of the patient.

BURROUGHS WELLCOME AND CO.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"New York Med. Journ.," September 23, 1905.

MALARIA. LECTURES ON THE DISEASES OF THE BLOOD. By JOHN M. SWAN, M.D.

"Riforma Medica," August 5, 1905.

SIGNORELLI, A. DISTURBANCES OF CUTANEOUS SENSIBILITY OF TUMOURS OF THE SPLEEN AND IN SPLENOPATHIES IN GENERAL. THE SPLENIC AREA.

Signorelli states that (*a*) "the splenic area" for clinical purposes is in the fifth intercostal space along the mammary line; (*b*) the "posterior splenic area" corresponds to the fifth, sixth, seventh, and eighth spinous process of the dorsal region; (*c*) "the lateral splenic area" exists in the intercostal spaces in the left mid-axillary line. These regions become sensitive in splenic derangements due to tumours or enlargement of the spleen. Corresponding areas of sensitiveness may occur on the right side by diffusion in exactly corresponding points to those described on the left side.

Original Communications.

FIT AND UNFIT PERSONS FOR RESIDENCE IN WARM CLIMATES.

By W. Hartigan, M.D., D.P.H.

It has occurred to me that a few notes, embodying the results of experience gained during many years' residence in the Far East, might be interesting and useful to those who, by necessity or inclination, are induced to make their homes and seek employment in tropical and sub tropical regions. This must be my excuse for the following article, which makes no pretence to be a learned disquisition on climatology, but is simply a series of practical hints from a practising physician.

Whilst living in China I had often noticed how many more or less delicate men had been advised "to go out East, as they would be sure to improve," and now, when examining in London for various Far Eastern firms, I have frequently to reject applicants as "unfit" who had likewise been told that "they ought not to remain in England, but would get on capitally in China, or Burmah, or Peru, as the case might be." Such advice has usually not been given by those who have had tropical experience, or made a a special study of epidemiology, but by the generally well-informed, thoroughly practical family doctor, in whose ken any distant clime, with a bright sun and tropical foliage, where an open-air life can be enjoyed, is just the place for the boy whose "lungs are slightly touched," or whose delicate physique unfits him for the rough-and-tumble of the football field, or who cannot bear the hardships of school life. This fallacy frequently gives rise to disappointment, and occasionally leads to disaster. It is true that exceptionally fine physique, great muscular development, or exuberant energy, are not necessary for healthy life in the Tropics. In my experience, wiry men, of medium height and slight build, even though a little under weight, of an active disposition, but not nervous temperament, do quite as well when transplanted to the East as the herculean gladiator of the playing fields or the madly enthusiastic gymnast. These latter (certainly when engaged in office work) seem to give way more to tropical *ennui*, become lazy, go in for verandah-life in a long chair, plus a whisky-and-soda, lose their energy, give up games and exercise, and soon "run to blubber." The nerve tone of the big man seems to be pitched in a lower key than that of his weaker brother, as if Nature would not pour out all her gifts on one subject, and balances the want of showy, physical attributes, by the gift of greater physiological resisting power against enervating climatic influences.

The great tropical explorers—Livingstone, Stanley, Emin, Johnston—men of superabundant grit and energy, were none of them giants, whilst it is an open secret that Lords Wolseley and Roberts, who have faced death and disease in every clime, would not "come up" to the present physical standard of an Army medical board. Careful discrimination must, however, be exercised. The weedy, narrow-chested, undersized, anæmic applicant, with thin, sandy or fair hair, pale pinched features, too clear or high-coloured complexion; and likewise the gawky, undeveloped, lanky skeleton, with straight, lustreless, dark hair, probably bright eyes, but sallow, jaundiced features; or again the physically well-built, middle-sized man, uncertain and slow of speech, with a dull heavy expression, and face of unhealthy colourless hue, phlegmatic, except when he enlarges on the state of his own health; are all equally unsuited for the Tropics. The former become early victims of tropical anæmia, with its consequences, loss of energy and inability to work, and readily succumb to prevalent intestinal diseases; whilst the latter develop into chronic dyspeptics, with a morbid tendency to introspection and dislike of companionship, which too frequently leads to secret tippling.

Another type to be avoided is the over-strung, exuberantly active, good-all-round, "admirable Crichton," who burns the candle at both ends, dragging through his long office hours with good grace enough, doing his work fairly well—for he has brains—but perhaps not very thoroughly, spending his evenings in theatricals or dancing, enjoying his little dinners and suppers, taking or giving "a peg" or liqueur at every opportunity; he has exhausted his reserves, and whilst he may get along happily enough in a temperate climate, will, should he go to the Tropics, almost inevitably become "jumpy" and hysterical, subsequently physically weaker, with progressive loss of weight, followed by loss of interest (if it ever existed) in work, incapability of concentrated application, degenerating into a childish state of "don't care"; in short, he has generally "gone to pieces" without any very definite reasons therefor. This condition is usually combated by frequent "nips," forenoon "cock-tails," and early morning "night-caps," eventually culminating in that well-known euphemism, "tropical neurasthemia," or "climatic dyspeptic gastritis," more correctly known as "chronic alcoholism," vulgarly "drink"; finally eventuating in "a passage home," with a polite intimation of "services being no longer required."

A tropical climate does undoubtedly "get on the nerves," but it is usually ably assisted by "Scotch," "Irish," or "Cognac," good, bad, and indifferent; nevertheless, the man of nervous temperament is not a good subject for the Tropics, whilst the victim of any of the neuroses is generally unfit for work or residence in hot climates. Asthma may probably be excluded from this generalisation, as supposing the asthmatic to have the power of selection, he may find a suitable place wherein he will enjoy almost complete immunity, but in the absence of such choice the Tropics and Sub-Tropics should be avoided. This prohibition applies also to the epileptic, even if only suffering from "petit mal."

Likewise the man of bibulous habits is most unsuitable; his thirst is certain to be aggravated, whilst the amount of liquor consumed with comparative impunity in Britain becomes a potent nerve-poison in the Tropics. He who has once been the victim of alcoholism, even if apparently cured, should never return to the East, the old temptation will grow with opportunity, an increased inclination will overcome an enfeebled resistance, "and the dog is returned to his own vomit again."

The slave of the pipe too, with blackened, carious teeth, irregular heart's action, short of wind; and the cigarette fiend, whose congested throat, dried, furred tongue and watery eye proclaim the chronic dyspeptic, will not improve in a land where cigars can be had for a few cents, and smoking is permitted and encouraged everywhere and anywhere. In moderation the fragrant weed is soothing and harmless, but when a pocketful of cigars can be smoked between early breakfast and tiffin, and the chimney is then kept going till bedtime, the result is a shaky, nervous individual, frightened at his own shadow, seeing fatal illness in every trifling ailment, imagining those he has not got, incapable of exertion, or breaking into profuse perspiration on making the most ordinary effort, unable to make up his mind on any subject, droning into unsympathetic ears his personal or business worries, who finally "goes smash," financially and morally, or goes home. This is not a fancy picture. I have seen it; *ergo* "*cave canem*." For such, "better fifty years of Europe than a cycle of Cathay."

To return to the point whence I started, in my experience the man whose lungs—to use the popular expression—are merely weak, has generally on his first arrival in the more healthy Tropics improved, particularly if he has previously enjoyed fairly good health; but should he unfortunately be attacked by malaria, dysentery, sprue, or other debilitating disease, which, however, he is not especially liable, the weak spot is sure to be found out and pulmonary disease follow.

If, however, there exists latent pulmonary disease, by which I mean a previous lesion at the moment quiescent, the damp tropical heat and super-saturated air, even in the absence of other illness, will almost inevitably cause a recrudescence of active disease in the impaired lung, which will rapidly break down under continued exposure to its unhealthy and debilitating surroundings; whilst, if foci of active disease are already present, evidenced by a general infection or enlarging cavities, the subsequent course is most rapid, either the cavities pour forth pints of stinking pus swarming with bacteria, or, the lungs rapidly solidifying, breathing becomes most laboured, expectoration, which may not be at all profuse, is full of tubercle bacilli, then high temperatures and exhausting perspirations, frequently followed by severe and repeated hæmorrhages, ensue; these rapidly wear out the patient, and death ends the scene in a few weeks.

We have all seen the girl, previously in apparently good health, with perhaps too high a colour, who, you are, told "has caught cold." You take a grave view of the case, but are not believed. In a few days her downward progress puts a melancholy end to the scepticism and incredulity of family and friends.

Or perhaps the athletic young man, often a Scandinavian or Dane, who knows he has had some slight lung trouble, tells you he has spat up a little blood which he thinks has come from the throat, and brings some blood-tinged, scarcely viscid sputum, in which tubercle bacilli abound. You recommend prompt departure for healthier climes; he does not or cannot take your advice; rapidly recurring hæmorrhages follow. He at last gets away, the hæmoptysis is checked, but irreparable mischief has been done, and he, too, succumbs, a victim of the too exuberant growth of the tropical forcing-house and of the mistaken advice which preferred "the nice warm climate" to his native northern snows. Sensible precaution can minimise the ill-effects of cold, which in many ways is most beneficial, but the deleterious qualities of damp heat are impossible to eliminate.

Although in my opinion *continued* residence in most parts of the Europeanised Far East is very detrimental to those phthisically inclined, the conditions obtaining in Hong Kong, Amoy, &c., during winter, and in Shanghai and Northern ports in spring and early autumn, may be actually favourable to them, whilst Chefoo and Wei-hai-wei are, even in summer, fairly good. Pekin, Tientsin, &c., being drier, are less objectionable (as all-the-year-round residences) than the South China stations, but the dust is a great disadvantage.

Japan, likewise, though better than South China or the Straits, cannot be recommended. Its climate is variable and damp; even the hill resorts, though ideal at certain seasons, are injurious for other and longer periods.

Manila, called in some geography books "a sanitarium," is also unsuitable. Damp and great dry heat alternate, the climate is most relaxing, intestinal complaints are prevalent, cholera epidemics far too frequent. Singapore, Penang, the Malay States, Burmah, Java, Seychelles, Mauritius, &c., are all objectionable, though some have hill resorts where the conditions are decidedly more favourable, but one must always remember that the man who is earning his living can very rarely take advantage of them, whilst the man of means will go to Egypt, or Davos, or California, where good air, comfort, and life-giving amusements all contribute to renewed health and vitality. I have purposely excluded the Riviera, having found its climate lowering, treacherous, and changeable, many of its popular resorts insanitary (in flies and smells they could favourably compete with "Eastern bazaars," or "China towns"), whilst, when the mistral blows, the dust is most irritating to delicate throats and bronchi: the sun and sky give them their only advantage over our cloudy land.

The man whose first object is "to get a living," and who can only afterwards indulge in the endeavour to keep alive, should seek an open-air life in Colorado, Arizona, or parts of South Africa, Australia, or New Zealand, &c. If he must dwell in cities, Sydney, San Francisco, Cape Town, &c., will afford him fair opportunities with comparative safety, but let him keep away from Eastern towns. With care, he would have as good chances of prolonged life at home.

In conclusion, I would say that the healthy, steady man, of slight physique, active habits and cheerful disposition, not necessarily a teetotaller, but temperate in all things, who recognises his duty to work as well as the necessity of play, need have no hesitation, should the glamour of the East allure him, in seeking "fortunes, buffets, and rewards," "at the quiet limit of the world," or in following a vocation which called him to labour in tropical vineyards. Of such it may not be said that "the eyes of a fool are in the ends of the earth," always remembering *in medio tutissimus ibis*.

THE QUESTION OF THE MODE OF INFECTION IN MALTA FEVER.

By Edward H. Ross, M.R.C.S., L.R.C.P.

Medical Officer, Sanitary Department, Port Said, Egypt.

Malta fever has been the subject of some considerable attention during the past few years on account of its ravages amongst the *personnel* of the British Army and Navy stationed in the island of Malta. Malta is the headquarters of the Mediterranean Fleet and possesses a large military and naval garrison with a total numerical strength of nearly 30,000 men. Amongst these Malta fever has had a fairly constant annual incidence of nearly 700. Owing to the prolonged nature of the disease a majority of the cases have had to be invalided home to England, and thus their services have been temporarily lost to the Empire. This disease, therefore, has been the cause of the expenditure of much of the public money and a notable reduction in the efficiency of our available fighting forces in the Mediterranean. In addition to this the people of Malta suffer greatly from Malta fever, which gives the island a bad name, keeping away visitors, and interfering with its commerce.

Malta, however, is not the only place where the disease is prevalent, for its existence has now been demonstrated in several of the seaports of the Mediterranean, the Philippine Islands, Hong Kong, &c. The name Malta fever, therefore, is hardly fair to Malta, nor that of Mediterranean fever to the Mediterranean; but the disease is now so well known by these names that a new one would be inconvenient and confusing.

Malta fever, then, may be defined as a prolonged fever which may be either continuous, remittent or even intermittent in type, usually exhibiting waves, undulations, or cycles of severity, and accompanied almost invariably by enlargement of the spleen, profuse sweating, and certain complications. It is caused by the *Micrococcus melitensis* of Bruce, which is found in the blood and blood-forming organs of men and animals suffering from the disease.

The waves of fever continue in the majority of cases for two or three months, but the disease occasionally aborts in two or three weeks, or it may continue for more than a year with apyrexial intervals. The mortality is low; in most years it is less than 3 per cent. The diagnosis of Malta fever does not, as a rule, present much difficulty; the prolonged nature of the fever, the accompanying sweating, the complications of synovitis, neuritis, and the persistent anæmia, in addition to the fact that the disease is only endemic in certain sub-tropical towns, renders the clinical diagnosis an easy matter. In a person living in Malta, or who has recently resided in Malta, who has fever which continues for two or three months, who complains of little but malaise, headache, pains in the limbs and joints, and who exhibits no physical signs save those of fever and enlargement of the spleen, and who has never shown the ordinary signs of typhoid, the disease is almost certain to be Malta fever. But in addition to the clinical aspect of the case the knowledge that the *Micrococcus melitensis* will agglutinate in the presence of immune serum is of great service. This serum reaction is fairly constant in its results and is of the greatest value as a confirmatory test in diagnosis. But it is not without its fallacies, for one occasionally finds variations in the agglutinating capabilities of apparently identical strains of the micrococcus, and thus confusing results are sometimes obtained.

The most conclusive means of diagnosis lies in the separation of the micrococcus from the blood of the patient; but this is not always practicable, and the fact that it could not always be carried out has diminished the value of much of the experimental work done. When obtained from the blood or elsewhere the identity of the micrococcus may be tested by its agglutination with immune blood serum, innoculation into susceptible animals and its subsequent recovery from them, its reaction to litmus, and negative Gram staining. Unfortunately it has not been in the power of many of us who have been investigating this disease to carry out all these confirmatory tests, so that the results of our experiments cannot be regarded as conclusive as might have been wished. But as a rule, save in exceptional cases, the diagnosis is easy and the work done must be valued accordingly.

There is no known specific cure for Malta fever, and up to the present time, according to the literature, not very much work has been done to obtain an antitoxin or a prophylactic serum for it; therefore it is necessary to find out how the disease is conveyed from one person to another in order to be able to take measures for its prevention. Having this object in view, Surgeon G. M. Levick, R.N., and myself undertook to investigate the disease by observation and experiment. After observing many cases of the disease from an epidemiological standpoint, we noted the following factors, and on these factors or postulates we based our experiments.

Postulate 1.—Malta fever is only prevalent in the towns near the coast of sub-tropical seas.

The only exception to this rule that we have, up to the present time, any reason to consider is the occurrence of Malta fever in Cairo. In this place the disease is said to exist, but beyond the statement to that effect we have but little proof of it at present. Judging by the only obtainable statistical returns, namely, those of the Army Medical Service, one finds that in the report for 1898, 191 cases of Malta fever occurred in the British garrison in Cairo; while in the reports for 1901 and 1902, when better methods of diagnosis had been instituted, and the disease better differentiated, the number of cases which occurred in in the garrison fell to 7 and 4 for the two years respectively; so that in the space of four years, and with the same numerical strength of troops—namely, 5,000, the incidence of the disease had diminished from 191 to 4; while in the contiguous ports of Port Said and Alexandria the disease had increased. The inference is that the existence of endemic Malta fever in Cairo is at present non-proven.

With this exception, then, so far as we have been able to find out, Malta fever is confined to seaport towns in the Mediterranean, in the Philippine Islands, Hong Kong, Cuba, and Bermuda, its existence in the last two places, as in India, being still doubtful.

So far as the Mediterranean is concerned the distribution is peculiar, for it is confined to the southern and eastern shores. Having visited many of its ports during the past eighteen months, we have enquired into the prevalence of the disease in each, with the following results: In some places cases of prolonged fever were examined by us clinically, and tested with the serum reaction, and were found to be cases of true Mediterranean fever—Corfu, Beyrut, Port Said, Malta. At the following places the disease has been identified by the local medical men, and tested by them with the serum reaction, and found to be prevalent: Tunis, Algiers, Athens, Alexandria. At the following places prolonged fevers are endemic, but we have been unable to find out if they have been definitely proved to be Malta fever or not: Smyrna, Constantinople, the Island of Lemnos, Oran. At Gibraltar, Malta fever was very prevalent two years ago, but from all accounts the disease has now almost disappeared, although at Algeciras it is still believed to exist.

On the northern shore of the Mediterranean the disease, if it exists at all, is very slightly prevalent; but we have not been able to obtain much information. At Toulon, and on the Riviera, it is absent (Shaw); at Barcelona it is probably malaria; at Genoa it is absent; but we have been informed that Neapolitan and Sicilian fever is true Mediterranean. With the exception of the case of Cairo above mentioned, our enquiries have led us to believe that the disease does not spread inland. It does not exist at Ismailia (Pressat), nor at Suez (Creswell), whilst at Port Said and Alexandria it is very prevalent; also three years ago the disease was present in Gibraltar, and is now at Algeciras, but not in the neighbouring Rhondda Valley, and while prevalent in Naples it is absent from Rome; so that we concluded that the disease is in some way connected with the sea, and this has consequently influenced our work.

Postulate 2.—Malta fever exists in endemic places all the year round, but its incidence is enormously increased in the hot weather, namely, from April until November, during the Mediterranean dry season.

Postulate 3.—In Malta the disease is especially prevalent in the hospitals in which cases of the disease have been treated, but it is not specially confined to the fever wards. Doctors and nurses in these hospitals frequently contract the disease.

It is very common for patients admitted to the Naval Hospital at Malta with surgical, venereal, or other affections to contract Malta fever after a stay there of a few days; and so commonly does this occur that it is sometimes necessary to question the advisability of sending patients to this hospital during the summer months.

The disease is also very prevalent in the Civil and Military Hospitals in Malta and in one of the hospitals in Port Said. In addition to this, it had been remarked by many observers, and by no less an authority than Hughes, that attacks of the disease may be localised to certain houses and barracks, and even to individual rooms, and to certain beds in a room. This, and knowing the fact that the disease cannot be conveyed by direct contact or by clothing worn by a patient, is of the utmost importance. Then, again, newly built houses and those near which building operations are going one, are specially prone to the disease.

Postulate 4.—Malta fever frequently occurs in epidemic form, the cases then invariably appearing one after another, not simultaneously, as if they were caused by a common means acting at the same moment. Examination of the recorded epidemics is very interesting in this respect, for those which occurred during the summer months show an interval of only one day between the cases, whilst in those which occurred during the cold weather this interval is often prolonged to three or four days.

Postulate 5.—Amongst the officers and men of the warships stationed in Malta the disease is, as mentioned before, very rife, but the manner in which these contract it is interesting. As a rule, when in Malta, these ships are moored in the harbours a short distance from the shore, which is steep-to; and amongst the crews of such ships the disease never occurs except in the case of men or officers who have recently spent the day or night on shore, or have a few days before returned from hospital. This fact we have verified by the most careful enquiries and observations. If, however, one of these ships goes into dry dock, or is moored alongside a wharf in Malta harbour during the summer, an epidemic of Malta fever almost invariably breaks out on board. The case has occurred when such a ship, having been in dock for some days, has then left Malta for a prolonged cruise, and a few days after leaving port an epidemic of Malta fever has occurred on board, one case appearing regularly after another with a one or two days' interval; and this has continued for two months, several of the cases then occurring amongst men who had not been out of the ships for weeks.

On these five epidemiological postulates we based our experiments, realising that infection in Malta fever is due in all probability to one definite and specific cause, which we determined, if possible, to find out, in order that prophylactic measures might at once be instituted.

This specific method of the transmission of the disease must therefore coincide with and account for all the above five postulales before it can be stated that the correct mode of infection has been discovered.

On my arrival in Malta in June, 1904, I associated myself with Surgeon Levick, R.N., and we agreed to start work at once.

The question then arose: Which would be the best method of working? We were then both surgeons in the Navy attached to different ships in the Mediterranean Fleet, and we knew that we should often be separated from one another, the ships rarely remaining in one port for any length of time, so that we could not experiment with monkeys or other animals; nor could we hope to make elaborate bacteriological analyses, for we were rarely at Malta, where, however, Dr. Zammit did his utmost for us; and we had no laboratories beyond the cabins in our respective ships. So we determined to repeat, so far as our circumstances would allow, the methods employed by Reed, Carrol, Lazear, and Agramonte for the discovery of the mode of transmission of

yellow fever, by endeavouring to obtain volunteers who with ourselves would be willing to undertake the experiments, to expose themselves to the probability of contracting the disease, and at the same time to live under such conditions as would reduce the possibility of error. Five others without hesitation at once volunteered to join us, so we determined to try upon ourselves every possible method of the transmission of the disease, and then by a process of exclusion eventually to hit upon the right mode of infection.

Up to the present time the *Micrococcus melitensis* has been found constantly in the blood of patients suffering from Malta fever, even in such a smal quantity as 5 milligrammes of the peripheral blood, and it has been found to be excreted intermittently in the urine; so that the possible modes of infection in Malta fever as in other analagous diseases are as follows:—

(*a*) By direct contact with Malta fever patients.
(*b*) By the clothing which has been worn by Malta fever patients.
(*c*) By urine-infected dust.
(*d*) By urine-infected water or food.
(*e*) By biting insects.
(*f*) Transmission in some way from some intermediate host.

Our first care was to assure ourselves that we were not immune to the disease; but as none of us had had Malta fever, and none of us had spent many months in the Mediterranean, and none of us had ever had any serious illness, we concluded that we were, some of us at all events, capable of contracting it. In addition we have all from time to time been tested with the serum reaction and this has always given negative results.

At first we proposed to experiment with artificial cultures of the micrococcus, but after much deliberation we realised that the results so obtained could only be inconclusive, for Nature does not work with agar cultures; and it is difficult to believe that under any natural conditions could the micrococcus occur in such numbers, such a degree of concentration and freedom from contamination as it is found when planted out on agar in the laboratory. As we could not afford to try experiments when their results would be inconclusive, we postponed the use of cultures until every other method of the transmission of the disease had been tried and failed.

We therefore decided to imitate natural methods as far as possible and to avoid artificially prepared materials for our experiments. From the outset we encountered some difficulties, as might have been expected. Chief of these was that we were constantly being separated, so that instead of being able to carry out the experiment with all the non-immunes simultaneously, we, as a rule, had to be content with three or four, and therefore each experiment had to be repeated and its result confirmed. Then we experienced great difficulty in obtaining materials to experiment with. Thus we frequently wanted to examine several patients in the hope of discovering some fact which would throw some light on the problem before us, or we wished to obtain urine from a patient, especially when it was known to contain the micrococcus, or we desired to allow recently hatched mosquitoes to bite a patient, who was willing that it should do so, in order that it might subsequently bite us, but we often encountered every conceivable opposition from those who had charge of such patients, and by those who are kept constantly acquainted with the ravages of the disease and apparently regard it in a state of lethargy from which it is impossible to wake them. Our work, therefore, is not as complete as it should have been had we been enabled to take advantage of every opportunity.

(*a*) We first considered the possibility of the transmission of Malta fever by direct contact. The possibility of this is remote, for although Malta fever is very prevalent in hospitals in Malta and other places where the disease is endemic, yet every year hundreds of men suffering from Malta fever are invalided to England and are treated in the naval and military hospitals at home, but the disease has never been known to spread in these latter hospitals; nor have nurses or orderlies ever been known to contract Malta fever at Haslar, Netley, Chatham, or Devonport. Nevertheless, as the opinion has been expressed that "One is driven to accept tentatively the unwelcome conclusion that Mediterranean fever is probably of a directly contagious nature" (Shaw), we attempted to reproduce the disease in the following way: A man suffering from Malta fever contracted in a Malta hospital was nursed in the ordinary sick-birth of a warship for a month by some non-immunes, who were in daily contact with the ship's company, but none of them contracted Malta fever.

This was repeated in another ship with another patient with the same result. Then on two separate occasions two non-immunes slept in the bedclothes which had been used by Malta fever patients, and still none of them contracted the disease.

This mode of infection does not agree with any of our postulates except possibly No. 3.

The conclusion is that the disease cannot be contracted in this way.

(*b*) Infection by clothing

Nightshirts which had been worn by Malta fever patients were conveyed on board four different ships and there slept in by four different non-immunes. They all remained well.

This mode of infection can only possibly agree with postulate 3; but it will not account for the increase of the disease during the hot weather nor its prevalence in ships which have recently been in dock. Then if the disease was transmitted by clothing or fomites it ought to spread in England; but it does not.

(*c*) Transmission by urine-infected dust.

In Malta, during the summer months, there is an almost complete absence of rainfall, and in consequence dust is blown about everywhere; in Malta, also, some of the people have an unpleasant habit of urinating in the streets, and therefore it seemed possible that the dust might become infected with the micrococcus excreted in the urine, and so passed from one man to another. It has been held that this is the chief means of the propagation of the disease.

We therefore mixed urine obtained from a Malta fever patient with some dust, and this was sniffed up the nostrils by two non-immunes, but they did not

contract the disease. This experiment was then repeated by four non-immunes, with the same result.

Unfortunately we were not in a position to demonstrate the presence of the coccus in the specimens of urine employed in these two tests; but as one of us had, previous to our determination, mixed a living culture with some dust and inhaled it without deleterious consequences, we did not repeat or continue dust experiments.

Infection by dust will not explain the prevalence of the disease in hospitals, nor epidemics on board ships when at sea. It is impossible to believe that a particle of infected dust should strike the nostrils of John Smith lying in Z Ward of the Naval Hospital at Malta, the remainder of the patients in that ward escaping, and another particle of urine-infected dust should strike the nostrils of William Jones lying in the same ward of the hospital three days later, and so on. Also ships at sea do not contain dust. This dust theory will not agree with postulates 3, 4 and 5.

(*d*) Infection by urine-infected water.

"The water-borne theory is on all sides considered improbable" (B. Smith). Epidemics do not follow the course of the water supplies in Malta. The incidence of the disease does not follow the course of that of typhoid. Hospitals are usually the last places to consume polluted water, and on board the ships of the Navy the water is distilled when at sea.

Infection by drinking water will not agree with postulates 3, 2, 4, and 5; but to make sure we mixed urine from a Malta fever patient with some water, and this was drunk by six non-immunes and none of them contracted Malta fever.

We made no experiments with food apart from water, except that four non-immunes drank some goat's milk which contained diluted urine in which the micrococcus was present, and they all remained well.

(*e*) Infection by biting insects.

I have stated elsewhere the opinion that this is the common and specific mode of infection in Malta fever, and up to the present time have met with no reason to alter that opinion.

Of all the methods of infection this seems to be the most probable one. It is the only one which will agree with all our postulates.

(1) The disease is endemic only in certain places; then it is probably conveyed by some insect which only inhabits these certain places.

(2) Malta fever occurs in the endemic areas all the year round, but its incidence is enormously increased during the summer months; some mosquitoes and biting flies live and bite in these endemic areas all the year round, but all biting insects increase enormously during the hot weather.

(3) Malta fever is specially prevalent in the hospitals where cases of the disease are being treated. When we know that it is not directly contagious and cannot be conveyed by infected clothing the insect-borne theory will alone explain the marked prevalence the disease has in hospitals and among nurses and orderlies in them. In hospitals, of all places, water and milk should be carefully sterilised and food carefully prepared.

Then the predilection Malta fever has for certain houses, rooms, and even beds, can only, in the absence of the conveyance of the disease by direct contact, or by clothing, be explained by the insect-borne theory. These last factors favour the transmission being by mosquitoes rather than by flies, for a mosquito will remain in the same room of a house or ship for months, so long as it can obtain a sufficiency of food in it.

(4) Then, again, during epidemics persons commonly contract the disease one after another in the hot weather, the interval between the cases being then short, for the mosquitoes feed regularly; but this interval is increased to two, three, or more days when the weather is cold, and when the digestive periods of insects is prolonged during partial hibernation. Mosquitos rarely fly off to the men-of-war in Malta harbours, but if a ship goes into dock then she is at once invaded by these pests and an epidemic occurs. Sometimes when such a ship goes to sea the epidemic continues because the insect remains on board conveying the disease from one person to another with a regular interval corresponding with its digestive period.

(5) Then amongst the crews of the men-of-war which have not recently been in dock the disease does not occur except in the case of men or officers who have been on shore a few days before. Every one on board necessarily consumes the same food and water, and fresh milk is never obtained by the men, so that this means of transmission by food and water seems improbable, and men must become infected by insects when on shore. The British sailor does not, as a rule, when he goes on shore at night on the spree, drink MILK.

We have experimented with many kinds of biting insects by making them imbibe the blood of patients suffering from Malta fever, and then allowing them to bite as many non-immunes as it was possible to arrange; but owing to the fact that we were living on board ship we had often the greatest difficulty in keeping the insects alive and making them bite regularly. In the case of *Acartomyia zammitii*, a mosquito which passes its larval stages in concentrated sea-water, which we have found in every place in the Mediterranean where Malta fever is known to be endemic, and which we in confidence thought to be instrumental in conveying the disease, we have been quite unable to make it bite regularly or to live long enough, with the means at our disposal, to give conclusive results. Had we been able to let loose in a mosquito-proof room a few infected mosquitoes of various species, and then been able to sleep in that room one by one, I am sure that we should have all of us contracted the disease, and its means of transmission been proved. Nevertheless, we did succeed in experimenting with some of the common species—namely, *Culex pipiens*, *Culex fatigans*, *Stegomyia fasciata*, and with fleas and bugs, but we did not apparently hit upon the right insect, for none of us contracted the disease.

Apart from this, very little work has been done upon this mode of infection in Malta fever. The Mediterranean Fever Commission has, it is true, made some experiments with *Stegomyia fasciata*, but so far as I am aware no other species of mosquito or kind of insect has yet been tried. Zammit claims to have succeeded in transmitting the disease from one monkey

Assist. Paymr. L. Blackler's appointment to the *New Zealand* has been cancelled.

HEALTH IN HOT CLIMATES.

Lieutenant-Colonel Giles, late of the Indian Medical Service, has produced "A Popular Treatise on Personal Hygiene in the Hotter Parts of the World." It should be of inestimable value to those who have to spend their lives in climates which differ radically from those in which they were born. The merit of the book lies in its clearness and simplicity. Taking it as a guide, an Englishman might provide himself with an ample medicine chest, select the best site for his dwelling-place, and have it erected on the soundest plans. He might thereafter, if far away from medical advice, guard against dangers to health, and deal with the earlier stages of such ills as may arise by simply using his commonsense under the precise and lucid directions given in various chapters of this book. In the opinion of the author, while it if hopeless to expect that anything in the way of actual colonisation can succeed in the climates with which he deals "with due care and attention to sanitary laws, as modified by the altered conditions, there is no reason why the rates of sickness and mortality should be much more formidable than elsewhere." Knowledge has increased enormously, and it is the application of it in daily life that is now most necessary. A very valuable feature of the book is that in which carefully-selected information is given about climatic conditions in various tropical countries. Colonel Giles expresses the surprise he experienced when, in collecting material for this section, he found himself "engaged in the preparation of what is really a pioneer work on the subject in the English language. But the slight efforts made to provide such data in a convenient form is suggestive of that carelessness which has led to the sacrifice of many lives. Much of the volume deals with India, where, as the author points out, the non-medical European has often to take measures for the protection of the indigenous community in cases of plague. Advice to all such is given along with good counsel as to the best ways of inducing the natives to accept sanitary precautions. Such a book as this should be regarded as a necessary part of the outfit for everyone going to reside in a tropical climate, and a careful study of its contents will be the best preparation for the dangers to health that may be encountered.

* Climate and Health in Hot Countries. By Lieutenant-Colonel Giles, M.B., F.R.C.S. London: John Bale, Sons, and Danielsson (Limited). 7s. 6d.

MEMORIAL TO LORD CHICHESTER.

TO THE EDITOR OF THE MORNING POST.

SIR,—All those who honoured and loved Francis Pelham

to another by *Stegomyia fasciata*, but he has been unable to confirm this result, and our experiments with this species have failed.

Apart from these experiments this mode of infection has been ignored, so that there still remains a great deal of work to be done before it can be said that this mode of infection can be excluded. Some arguments have been adduced against it, but they may be readily dismissed. The argument that because typhoid is not insect-borne Malta fever cannot be is not reasonable. It has been stated that the *Micrococcus melitensis* has not been discovered in sufficient quantities in the peripheral blood to render it possible for insects to infect themselves by biting Malta fever patients. This argument was made much of three years ago before the micrococcus had been discovered in the peripheral blood. It was repeated after it had been discovered in the peripheral blood. It was again repeated after it had been demonstrated in 1 cc. of blood. It was again repeated after it had been separated from 0·0005 cc. of blood. Perhaps it will be again repeated when it has been found in 1 milligramme of blood. It seems probable that the zenith of bacteriological method has not yet been arrived at.

Then it has been stated, "No known disease of bacterial origin (as contrasted with those of protozoal origin) has yet been proved to be insect-borne." Have we, then, so fathomed the depths of Nature's methods that we can afford to dismiss a possibility like this on the strength of a negative analogy?

The Mediterranean Fever Commission has produced the disease in monkeys in a variety of ways. These monkeys were kept chained to cages placed close together on an open stone causeway at the Public Health Laboratory at Malta.

Dust which had been mixed with the whole contents of three, four, or more agar cultures was blown into a monkey's cage periodically from July 10th until August 26th, and it was not until the latter date that the monkey showed signs of Malta fever. This was repeated in another monkey, only the dust in this case was blown up its nostrils. This was continued almost daily for a month before the monkey contracted the disease. Some monkeys were fed daily on whole agar cultures for more than a month before their blood reacted. These monkeys required, on the average, to be given the growths on twenty-seven agar slopes before they contracted Malta fever. These animals are always gnawing at their chains or the bars of their cages, and during the dust experiment had to be gagged, so that it is difficult to exclude the possibility of infection through the sores and abrasions thus caused, and the same applies to experiments with goats.

It is impossible to believe that under any conditions in Nature could a man partake of the number of micrococci found on twenty-seven agar slopes. If the minutest quantity of a culture of the micrococcus is placed under the skin, the disease is invariably produced after an incubation period of about six days; whereas these monkeys had to be fed for weeks before they contracted the disease.

While these experiments were going on, two other monkeys which had not been the subjects of any experiment at all contracted Malta fever. Some monkeys which had been the subjects of contact experiments also contracted it. Subsequently some other monkeys which had received injections of epidermal scrapings gave temporary reactions to Malta fever after varying intervals, but these were ascribed to the action of toxins, paddling about in infected urine, or to *Stegomyia*.

But is it not possible that these monkeys which contracted the disease "naturally," as Major Horrocks calls it, in reality contracted it in the only way in which it is commonly contracted, and the only way which has not been the subject of thorough experiment? One cannot help thinking that perhaps some of the monkeys which were the subjects of experiment also contracted the disease "naturally."

None of these monkeys were kept under mosquito-proof conditions, and consequently these experiments lose much of their value. We know that the disease does not spread by contact, or by clothing, or by the sweat, or by the breath, for if it did we should have Malta fever every summer in England; so that the inference is that some of these monkeys which were supposed to have contracted the disease by artificial means in reality contracted it naturally. Perhaps an infected insect was hovering in the neighbourhood of these monkeys, and it spread the disease from one to another, their infection not being the result of experiment at all.

We ourselves have swallowed reasonable quantities of the micrococci under conditions which precluded the possibility of insect infection and we all remain well to this day.

(*f*) Infection in some way from some intermediate host.

During the winter of 1904-1905 we were informed by Zammit that he had found goats to be susceptible to Malta fever, and he subsequently discovered that a large percentage of these animals in Malta were actually suffering from the disease which had been contracted naturally. As a result of this the *Micrococcus melitensis* was looked for in the milk of these animals and found in it. It was therefore at once concluded that the disease was transmitted from goats to man through the medium of the milk. This discovery was published broadcast and the matter was, by some, considered finished, for it was supposed that the goats contracted the disease by eating offal in the streets. But it was then discovered by Zammit and Shaw that cows also were susceptible to Malta fever, and that some of the cows in Malta had also contracted the disease naturally. It was then suggested that cows also sometimes eat offal.

We were all very much struck by these discoveries, and in consequence I at once wrote to the Medical Superintendent of a hospital in which several cases of Malta fever had been contracted and in which the disease was actually prevalent at the time, asking him to put these discoveries to the test by carefully sterilising all the milk supplied to his hospital and to watch results.

This he did on receipt of my letter (August). Milk had always been carefully sterilised in his hospital, but he made doubly sure of it by superintending the sterilisation of it himself. The result was that not only did the disease continue to occur, but he himself,

alone of his household, having always disdained the use of mosquito netting, first contracted benign tertian malaria and then a severe attack of Malta fever, from which he is still suffering.

In the meantime, on our return to Malta we determined to try the effect of drinking naturally infected goat's milk on as many non-immunes as it was possible to collect together in the short time we had at our disposal (seven days), but we were very disappointed to find that we could not obtain the milk in which the presence of the micrococcus had been demonstrated, so we had to be satisfied with the following test. We mixed a large loopful of a living culture of the micrococcus with some goat's milk, which, after keeping a few hours, was drunk by four non-immunes. One of these kept the milk too long, for after drinking it he had an attack of vomiting, but the others retained it well. To our astonishment nothing occurred, all the non-immunes remaining well; but we realised that at the best this experiment was artificial as we had used an artificial culture, but we were quite unable to obtain naturally infected milk. When we considered, however, the results of this and our former experiments and that all epidemiological factors point most strongly to the disease being insect-borne and against infection by the alimentary canal, we sought an explanation of the disease occurring alike amongst men, goats and cows under the insect-borne theory. We therefore debated the possibility of Malta fever not being conveyed by milk or the eating of offal, but by insects which transmitted the disease to all these animals. If this was the case, then one would expect that some other animal which did not under any conditions eat offal or drink milk, and which lived in Malta, would also commonly suffer from the disease.

I, therefore, being away from Malta at the time, wrote to Dr. P. Micallef, of the Public Health Department in that Island, asking him to examine the bloods of as many horses as possible to see if any of them reacted to Malta fever.

This he did at once. He has examined up to the present the bloods of thirty-eight horses of which four reacted to Malta fever. As one cannot accuse horses of eating offal in the streets or of drinking goat's milk, and taking into consideration our experiments and the epidemiological factors herein set down, one must conclude that although the micrococcus is present in goat's milk and is excreted in the urine of men and animals suffering from the disease, yet it is in all probability not conveyed by the drinking of milk or the eating of offal, but by an insect, as yet undiscovered, which transmits it from person to person, goat to goat, cow to cow, and horse to horse, and possibly from one of these animals to the others.

Lastly, from the epidemiological factors and the experimental work done, the possibility of the disease being conveyed by dust, water, food, or direct contact seems highly improbable.

It behoves us all, therefore, who are in daily contact with the disease, or who are interested in it and are able to do so, to search diligently for the mosquito, biting fly, or other insect which conveys it, and when found to institute means for its extermination.

THE MOSQUITO WORMS OF TRINIDAD AND THEIR REAL NATURE.

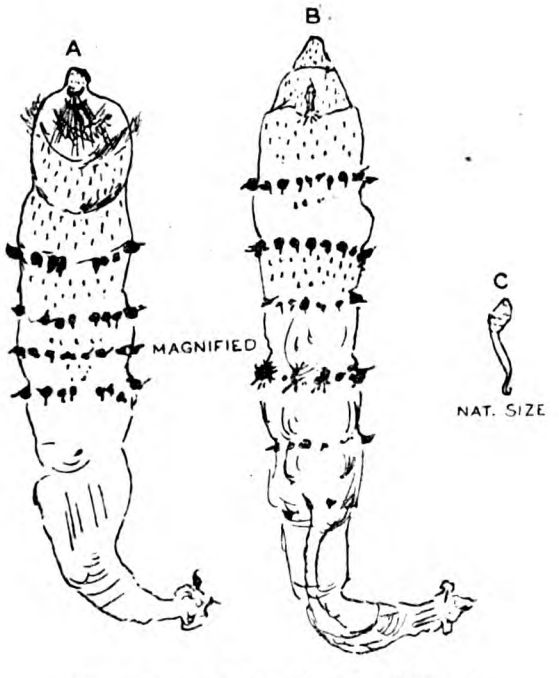
By A. J. B. Duprey, M.R.C.S., L.R.C.P.
Mayaro, Trinidad, West Indies.

In Trinidad, more than any of the other West Indian Islands, cases of external myiasis are not of infrequent occurrence. This is especially the case in this district, where the presence of various parasitic diseases is mostly due to the extensive tracts of purely virgin forests in an, as yet, uncultivated part of the country, and in which abound all kinds of biting and venomous animals. The traveller in these forests will experience very great annoyance through a myriad of flies and other insects of all sorts and sizes, some even beautiful and glittering in their varied colourings of blue and green, keeping up a continuous buzzing for miles of forests through which the wayfarer travels. Fortunately for man, who is well able to defend himself, these flies, with the exception perhaps of the undaunted mosquitoes, do not often attack him; but the poor animal which he bestrides is not infrequently blooded to a considerable extent. Often the hunter or the planter, after his bush excursions, finds that he has been bitten, as he thinks, by mosquitoes, which fact in itself is not at all surprising, but he discovers later that there are four or more very irritable and bumpy spots about his body, usually on the hands and face, sometimes on his legs, for which he cannot account. The experienced bushman knows these to be mosquito worms, and awaits patiently for a day or two, when the worms shall have matured, and forthwith takes the necessary steps to rid himself of them. The uninitiated, however, continues to rub the irritable spot until he finds that, instead of subsiding, a not inconsiderable blush of inflammation has spread around the original bump, where he may notice a small aperture about the size of a pin's head, from which exudes a sero-purulent discharge. A knowing one now sees this inflamed spot, and at once recognises the nature of the condition; he proceeds either to squeeze out the worm, or, if the part is very painful, he applies a little plaister over the aperture usually, among the labourers, made of brown paper coated over with a soft tallow. The worm being an air-breather soon dies, after which it can be readily squeezed out. On account of the knowledge and experience which the labourer has of quickly ridding himself of this worm a case is seldom allowed to go far enough to require the services of a medical man, so it comes about that the doctor rarely sees a case. I had the opportunity of seeing a very severe case of so-called mosquito worm infection a short time back, and as I had no idea of what a mosquito worm was I was naturally much interested in the case.

The patient had been out on an excursion in the woods for the greater part of the day, and, as a consequence, was infected in the lower third and outer aspect of his left thigh, where there was to be seen a round hole about the size of a No. 9 shot, from which pus exuded on slight pressure. The surrounding inflammation was fairly extensive and indurated, of a bright red colour, and acutely sensitive. The constitutional symptoms were severe: he had a thickly coated tongue, a febrile pulse, and really looked very

pale and ill. On the front of his leg on the same side there was an angry and weeping eczematous eruption, probably also of a parasitic nature of some kind, which easily subsided on treatment. A little 1 in 40 carbolic lotion syringed in the aperture quickly killed the worm, and on the following day, after the subsidence of the inflammation, the worm was extracted. This latter was not kept for my inspection, but the gentleman gave some description of its appearance which caused me to think it was the larva of the *Dermatobia nonialis*. An abscess developed in his thigh, which was opened a few days after by a doctor in Port of Spain.

Some weeks after another gentleman came to show me several little swellings on his face and hand, which he said were mosquito worms. There were no less than four on his chin, over one of which he had placed the proverbial plaister, and one on the back of his left hand. The swelling over which the plaister was placed was the size of a pea, and two small holes could be seen where entrances were effected. The bump was very painful on pressure, and the man said that the worms were not ready to be squeezed out, but that he would return on the morrow. The little swelling on his hand was a mere papule, in the centre of which was the minute aperture of entrance, very much like a mosquito bite (hence the name of mosquito worms). It was extremely irritable, and I noticed the man rubbed it continually. On the morning of the next day he came again, when I squeezed out two little worms from his chin quite close to one another, from the examination of which I made the following drawing.



Dermatobia nonialis "Mosquito Worms."

The larvæ belong to the genus *Dermatobia*, which are variously described by authors; the length and size vary considerably according to the stage of development. The larvæ are whitish in colour and club-shaped, the handle-part of the club or posterior extremity being furnished with the respiratory apparatus. There is, I think, some mistake made with regard to the mode of infection. The larvæ are described as though the fly actually deposits her eggs directly in the skin of man, dogs, or wild animals. Scheube says "it mostly lays its eggs in the skin of cattle, sheep, and dogs, and sometimes in the skin of man"; and Manson, in his "Tropical Diseases" (1898 ed.), says the same. Daniels thinks "man as well as animals may be attacked." It may be said here that the fly never attacks man or animals directly, but that the eggs are deposited on leaves and branches in wooded lands and forests, and thus man, hunting dogs and other wild animals in passing through get the larvæ deposited on them accidentally. I believe this is evident from the fact that, though the affection is common in Trinidad, no one has as yet seen the fly or can tell in what way the worms get deposited on the skin. The presence of the *Dermatobia nonialis* is not even suspected, seeing that the worm is attributed to the bite of the mosquito. I am inclined to think, therefore, that the nature of the mosquito worms has never been recognised in Trinidad. I have never heard of the existence of the Dermatobia in the other British Islands of the West Indies.

IS MALTA FEVER PECULIAR TO MALTA?

By Llewellyn P. Phillips, M.D., M.R.C.S., F.R.C.S.
Cairo, Egypt.

In a leading article on this subject in the Journal of December 15th, you state that Malta fever is infrequent and rare elsewhere than in Malta. Now the following facts will show that it is far from rare in Egypt, the evidence for its occurrence not resting on clinical facts alone, but also on the agglutination test.

Cairo.—In Cairo this year five cases of Malta fever have been under my care, a short *résumé* of them being as follows:—

(1) A Coptic lady who lived in Cairo and who had not left it this year, called me in to see her in October; she had been ill for about three months with a fever which was constantly relapsing, and had been treated for malaria with no success. I suspected Malta fever, and had her blood examined by Dr. Dryer, the medical officer of health for Cairo; it was found to agglutinate the *Micrococcus melitensis*. She had a subsequent relapse, and still remains ill.

(2) Another Egyptian called me in a few days later, and told me that he had Malta fever. He lived some six houses away from the preceding case in the same street. He had been ill for about eight months. The original attack occurred in Cairo, but was not suspected. He then went down to Alexandria, where a relapse occurred. An agglutination test was then applied, and gave a positive result of 1 in 500. He then went after that to Vienna for the summer, and promptly had another relapse. Professor Nothnagel saw him there, and had a further blood examination made. This was positive in a dilution of 1 in 1,000. When I saw him he was in his sixth relapse, which

was of the undulant type, and proved to be the last. In December his blood was again examined and agglutinated the *Micrococcus melitensis* in a dilution of 1 in 300.

(3) A Berberin servant living in Cairo was admitted to Kasr el Ainy Hospital under me with what I at first diagnosed as rheumatic fever, there being pains and sweats; a systolic mitral murmur developed. He was put under salicylates and kept on them for ten days, but with no effect, so I stopped them; the temperature then ran up to 105°, but came down with cold sponging. I now had his blood examined, with the result that it agglutinated the micrococcus of Malta fever. Meanwhile I put him on liquor hydrargyri perchloridii in drachm doses, his temperature came down and remained down, and he slowly got well.

(4) A Cairo policemen was attending my out-patient department for some weeks with what was apparently chronic rheumatism. Two weeks running his temperature was 100°, so I had a blood examination made by Dr. Ferguson, with a positive result for Malta fever. He, however, refused to be admitted into hospital.

(5) This was the case of an Englishman who was employed in the Cairo police stores. It is particularly interesting, as he had a double infection with typhoid fever and Malta fever. I intend publishing the case in detail shortly.

He was taken ill in September with diarrhœa and fever, and in fact went through a severe attack of typhoid fever, with a positive Widal reaction. He was very delirious and nearly died. This was followed by a relapse of the same nature. After an interval of some twenty-five days again he had a relapse, with signs of bladder irritation. The fever did not, however, subside, but became remittent in type; he having served in Malta some years ago he said he thought he had "slow continued fever," which he said was common in Malta, but which he escaped there. I had a specimen of his blood tested by Dr. Dryer, with the result that it agglutinated the micrococcus of Malta fever. A second specimen a week later still agglutinated the *Micrococcus melitensis*, but no longer agglutinated the typhoid bacillus. I treated him with sodium thiosulphate, as suggested by Dr. Betts, and found useful by him at Port Said, but with no effect. I then gave him perchloride of mercury as in the former case, with excellent results. In fact, I believe that perchloride of mercury given whilst the fever is coming down at the end of a paroxysm and continued for some time, is very efficient in cutting short the disease.

Besides these cases which were under me, there were several others admitted to the Cairo Fever Hospital, in whom the nature of the disease was proved by the agglutination test.

In Port Said there has been quite an epidemic of the disease, the doctor of the Government Hospital himself contracting the disease. Whilst under my care for it at Cairo, he told me that he had treated about a hundred cases there during the last few years, many of them being confirmed by the agglutination test.

I therefore consider that the fact is undoubted that Malta fever occurs endemically in Egypt.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 ,, ,, 6/-;
200 ,, ,, 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 ,, ,, ,, 11/-;
200 ,, ,, ,, 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

JANUARY 15, 1906.

A PLEA FOR UNIFORMITY AND GREATER OFFICIAL SUPPORT IN THE COLLECTION OF COLONIAL CLIMATIC DATA.

METEOROLOGY is a science that, perhaps more than any other, is dependent on amateur effort; for the professional meteorologist is one of the rarest of the scientific fauna; a dozen or so sufficing for the needs of even a good-sized kingdom. Many of our colonies are absolutely unprovided with specialists in this branch of knowledge, the work being handed over to the astronomer, where such a scientific luxury is indulged in, or elsewhere to the medical authorities "in addition to their other duties"; and everywhere the rank and file of the official observers are furnished by the medical services.

Doubtless, by virtue of his scientific training, the medical officer is usually the best man avail-

able for the purpose; but against this may be put the fact that, like a woman's, a doctor's work is never done, so that he is liable to be called away at any time and so perforce neglect this less important item of his duties.

Now, to be of any real value with the customary equipment, meteorological observations must be taken punctually at stated times, and it would therefore be probably better if more usually engineering officials, who are less liable to irregular calls, were chosen for these duties.

As matters stand, the actual taking of the observations must necessarily be often deputed to native assistants; and the result is that personal observation becomes irregular, and the medical officer necessarily loses the personal and continuous interest in this branch of his duties, which alone can secure valid results.

During the writer's work in unearthing climatological data from official sources he met with the most ludicrous instances of this sort.

Observations at stated hours recorded as above the maximum or below the minimum of the same days; wildly impossible readings of the differences between the wet and dry bulb thermometers and deliberate fudging. In one case an entire year's observations were cooly copied, figure for figure, from a previous year. Of course such a case as this implies not only neglect of personal observation but an entire absence of any attempt at supervision. Such lapses are, however, far more excusable than at first sight appears.

The most exact and careful series of personal observations may be utterly spoiled by the advent of a baby or a surgical emergency, and practically the actual observation must often be left to a ward coolie or even a private servant, who at most can barely read.

Under such circumstances it is impossible for the work to be *well* done, however keen the medical officer may be; and no man can be fairly expected to take a genuine interest in any work unless he is so circumstanced as to be able to do it thoroughly.

Under these circumstances it is by no means surprising that one has to exercise considerable care in selecting observations, and must needs often reject a large proportion of those recorded or purporting to be so.

In one case, indeed, a discriminating superintending medical officer refused to record an entire year's observations, as he had convinced himself that they were entirely valueless.

This condemnation was probably too sweeping, as the records were probably neither better nor worse than the average, and doubtless included many that could be picked out by an expert as sufficiently reliable for inclusion as components of averages; but it is obvious that the administrative officer could not take this course without exposing to reprimand overworked officers, excellent and energetic in their proper duties; and whom he knew under existing circumstances could not fairly be expected to take any genuine interest in this by-path of their work. To expect observations at stated hours from medical men of any class is to demand an impossibility, and the farce of attempting to do so should cease. When no other observer is available the observatories should be supplied only with self-recording instruments, which can be recorded and set at almost any time of the day.

Instead of this, however, the equipment of colonial observatories is of the most variable and often of a needlessly complicated sort. Moreover, even where observations taken at stated hours bear the impress of care and exactitude their value is greatly discounted by the fact that they are not uniformly taken at the same hour, even within the limits of a single colony; and are, therefore, useless for purposes of comparison, and after all the main value of all such observations is comparative.

The reason for this deplorable want of system and wasted labour and opportunity are not far to seek, and lie in the fact that, in spite of the enormous extent and value of our Colonial Empire, this rich country does not afford itself even a single specialist to collate and systematise the reports coming in from all parts of the world, on a subject which may, without exaggeration, be affirmed to afford some of the most indispensable data for all rational sanitary and economic progress. Without this knowledge the sanitarian

is unable to pronounce what measures promise best for the vulnerability of the parasites which cause most tropical maladies of man and beast, as these depend more than anything on the intelligent application of an accurate knowledge of the climatic peculiarities of a region — while on the economic side, who can say what sites are likely to be suitable for the growth of cotton and other crops, without accurate and systematic information on this vitally important subject.

Enormous sums have been and are being wasted on bootless experiments of this sort; while a tithe of the cost would suffice to equip and maintain an adequate colonial and central staff for the collection and publication of this most indispensable class of information; but just as our armies have had to blunder through unmapped areas of our own territory, so must those who would exploit the latest resources of our colonies blunder into unknown climates.

Let us hope that our new Liberal Government will show itself liberal in more than name in this matter, for it is humiliating to turn from the climatological returns of our own colonies to those of other governments, which usually show a much better claim to the title in the best interpretations of the word.

Science, however, in any form can expect little encouragement from any English government, but pending the unfortunately very unlikely consummation of money being spent on this most important and certainly remunerative object, something at least might be done in the direction of uniformity and in the simplification of the equipment of observing stations. With the exception of observatories at the seats of Government where a specially trained subordinate should be detailed for the work, in addition, perhaps, to clerical duties, all observatories working at stated hours should be done away with, at any rate, if they are to be conducted through the agency of the medical services. Barometric observations have but little interest to the climatologist, and are only useful for weather forecasts when combined with simultaneous telegraphic reporting over large areas; and such observations might very well be omitted from the ordinary stations, which should be equipped with only a rain gauge and maximum and minimum dry and wet bulb thermometers. Under this system five instruments only would have to be attended to *once a day*, and it would be a matter of no moment what hour of the day was selected for the purpose; nor, within very wide limits would it matter if the hours of observation were the same; though probably some time in the evening would be most convenient for the purpose, in which case the observations might be recorded at any time between 4 p.m. and midnight, at the observers' convenience.

A sixth column should be added to the form for a statement of the average amount of cloud, and in certain cases, perhaps, a sixth instrument might be added, in the shape of a wind vane.

The data suggested afford the maximum and minimum and range of temperature of the day definitely, while in the case of temperature the average of the maximum and minimum approaches so closely to the true mean temperature of the day that it is adopted as such in many countries. It also furnishes definitely the maximum and minimum relative humidity of the day, and the average of these, though constantly less than the true mean, is exactly comparable with the means of other stations where the same system is adopted.

It gives also the amount of rainfall and the number of rainy days, while the complement of the amount of cloud gives the proportion of insolation received at the station. The monthly and annual means derivable from these figures should be calculated at the station of observation, but it is better that the calculation of the relative humidity, from the wet and dry bulb data, should be left to those who make use of the information, as it introduces a second source of error, and so renders the value of the records less easily appraised by the expert.

The "screens" for the exposure of the thermometers should be of uniform pattern, and should, in all cases, be placed beneath a thatched shed about twelve feet in diameter, open at the sides, and well clear of neighbouring buildings, and the site chosen should be one which the

observer must visit in the course of his other duties in the evening, or be placed near his private quarters. The form of record would then run as in the example below.

STATION, *Jaipur*. LAT. *26° 55'*. LONG. *75° 50'*.
HEIGHT ABOVE SEA, *1,430 feet*. MONTH, *May*, 1907.

Date	Dry Bulb Minimum	Wet Bulb Maximum	Dry Bulb Maximum	Wet Bulb Maximum	Rainfall Inches	Proportion of Cloud	Remarks
1	79·2	66·1	104·5	80·2	0	1	*Heavy dust-storm*
2		&c.,	&c.,	&c.			
31							
Means*							

Heaviest rainfall of a day, . Number of rainy days, .
Signature.

* NOTE.—In the case of rainfall, the total and not the mean of the month should be given.

It may be fairly claimed that all really important climatological data are included in the scheme outlined; that the facts required can be collected with the least possible trouble to the observers, and, the most important of all, that they are easily comparable.

Lastly, it may be pleaded that the reform is one that would cost nothing more than the few shillings required for the purchase of the two wet bulb thermometers, and that it can be effected literally by a stroke of the pen of the Colonial Secretary.

CO-OPERATIVE RESEARCH IN CLIMATOLOGY.

IN presenting to our readers the first "Climate" issue of the JOURNAL OF TROPICAL MEDICINE, the Editors desire to impress upon the alumni of the Livingstone College who have done so much to give interest to the pages of CLIMATE, now incorporated with this publication, that they look to them to continue the literary and material support afforded to its predecessor.

No class of men are better placed than the ex-students of that College for prosecuting and advancing the study of climatology, for they penetrate to the uttermost corners of the world, and are often stationed for long periods, where other white men at most pay only flying visits, and they can thus render immense service to science by undertaking systematic observations at the scene of their labours.

The Jesuit missionaries have in a variety of localities done work of this sort of the greatest value, and surely Protestantism, which prides itself on its more liberal attitude towards science, should not allow itself to be put to shame by these self-sacrificing pioneers of civilisation.

The trouble and expense involved in systematic observations of this sort is singularly small, for the instruments can be bought for a sovereign, and five minutes daily is all the attention required. The Journal will be glad to furnish any gentlemen desirous of taking part in these investigations with a set of forms for each year's observations, and it is needless to say will gratefully publish the results when transmitted to them, besides which it is proposed to afford some little recognition of the service rendered to science by a complimentary gift of appropriate literature.

The Editors' idea is in fact to make the Journal the organising centre for the systematic extension of our knowledge of tropical climatology by the medical profession and the alumni of the Livingstone College. English meteorology would be in a most backward state but for the efforts of the Royal Meteorological Society, and it is our ambition to do something to emulate its invaluable work by organising the systematic study of the climatology of the back of behind. We indulge in the hope that a considerable number of gentlemen may be induced to participate in this scheme of co-operative research.

In the next (April) climatological number it is also proposed to include a short series of articles on the methods and aims of observations of this sort and the physical facts on which they are based.

DR. CHARLES F. HARFORD'S LECTURE AT CAMBRIDGE.

DR. HARFORD has devoted considerable attention to the best methods of interesting that section of the public who are concerned in various enterprises connected with the Tropics and especially those who go abroad as missionaries. His work has chiefly centred round Livingstone College, where a special course of training on well-defined lines is given to missionaries. Besides this he has organised several exhibitions of outfits for the Tropics and has sought to influence a larger circle by means of *Climate*. On Wednesday, November 22nd, 1905, Dr. Harford addressed a University audience in the anatomical theatre by the invitation of Professor MacAlister who, by a strange coincidence, was attacked by malaria on the very afternoon of the day, as the result of his

recent visit to Palestine, and so was unable to be present.

The lecture had the support of all the professors and teachers of the Cambridge Medical School, and Dr. Nuttall most heartily co-operated to make the occasion a useful one by arranging a demonstration of drawings of parasites and many interesting diagrams, and he, as well as Sir Patrick Manson and Major Ross, had lent many of the lantern slides which were shown at the lecture, which proved to be a valuable opportunity of setting forth the urgent necessity of spreading a knowledge of tropical health problems, and showing what is being done in this direction.

The chair was taken by the Master of Trinity who, in the course of a most interesting speech, strongly urged the importance of preventive medicine and illustrated his remarks by reminiscences of Jenner in the early days of vaccination. He also drew attention to the recent sanitary measures at Panama.

The lecture, which was entitled "Risks to Health in the Tropics: their Relation to Imperial Expansion and Missionary Enterprise," was a type of how a subject of the kind ought to be presented to the public. The necessity for educating the public in this country, in the meaning and nature of the chief scourges which attack our fellow-subjects in many parts of the Empire, may appear to many "stay-at-homes" of academic interest merely; but even to those who have never personally known what the dangers of a tropical climate are, but who take wider views of our imperial duties, let alone their humanitarian aspects, the subject of the health of both the white and coloured populations of the tropical parts of the Empire is one closely bound up with our daily life. If education in these matters is of direct interest to dwellers in these islands, how much more personal and immediate is it to the hundreds of millions of men and women who are exposed to the deadly diseases which prevail around them. Instruction how to protect themselves and to ward off disease from their children is a factor in their life which has hitherto been neglected; but, thanks to recent scientific discovery, it is now possible and ought to be the duty and pleasure of every man and woman who is capable of giving it. Dr. Harford brought out this point most clearly in his lecture and it is hoped his audience took the lesson to heart. Dr. Harford, in advocating the means whereby disease in the Tropics is to be fought, did not commit the mistake of advocating this or that nostrum, but strikes at the root of the matter by stating that the chief prophylactic measure we possess consists in the education afforded to medical men practising in the Tropics by the Schools of Tropical Medicine in London, Liverpool and Cambridge. He also pointed out what is being done at Livingstone College in educating missionaries in the rudiments of tropical hygiene. This most beneficent development is one of great national importance, for in many parts missionaries are the teachers of the children; and the education the missionaries receive at Livingstone College eminently fits them to give reliable instruction based on scientific methods in the schools under their charge.

At the London School of Tropical Medicine no fewer than 550 medical men practising, or destined to practise, in the Tropics, had already taken out the course of instruction provided by the School. The Liverpool School of Tropical Medicine had gained a world-wide reputation by the numerous expeditions it had sent to gather information and to teach how disease is to be prevented. The Cambridge School had placed its laboratories at the disposal of men interested in Tropical Medicine, and had raised the status of this branch of medicine by granting a diploma in Tropical Medicine and Hygiene. At the Livingstone College 248 missionaries have availed themselves of the privileges there granted them, and have gone forth equipped in a measure unknown to their predecessors in the missionary field.

The lecture at Cambridge was amply illustrated by lantern slides, and, like all "teaching" lectures, the bald text is apt to appear meagre in comparison to the actual instruction conveyed. Dr. Harford, in his lecture, stated the principal diseases met with in the Tropics, and showed how many of these diseases were conveyed, and how they were to be avoided. He showed by simple tables the meaning of heat and moisture in a tropical, compared with a temperate, climate. A short account of the malarial parasite, its development in the blood of human beings and in the mosquito, and its mode of transmission by a particular species of mosquito, was illustrated by lantern demonstrations. Yellow fever, filarial ailments, and tick fever were dealt with in the same manner; nor was ankylostomiasis neglected. The methods of stamping out malaria advocated by Major Ross, and successfully employed by him at Ismailia, and by Dr. Malcolm Watson at Port Swettenham, were cited as instances of how malaria may be prevented by the destruction of mosquito breeding grounds. Dr. Harford, in his summing up of the subject-matter of his lecture, again advocated the necessity of educating not only the medical men, but also the natives, and especially the children in the schools, in the manner which had been so successfully carried out in the colony of Lagos on the West Coast of Africa. J. C.

Reviews.

A Handbook of Climatology. By Dr. Julius Hann. Translated from the Second German Edition by Robert De Courcy Ward. New York and London: Macmillan and Co. Part I.

We have nothing but praise for this much-needed translation of Professor Hann's well-known work, as it forms the only available book on the general principles of climatology available to the English reader, in which the subject is at all exhaustively treated.

The original German work consists of three volumes, the second and third of which are devoted to regional climatology; and we think Professor Ward is well advised in confining his translation to the first volume, which deals with the general principles of the subject. Regional climatology is obviously better dealt with by local experts than by a writer whose experi-

ence is necessarily mainly confined to Europe. The book, however, is something more than a translation, for in addition to the examples cited by the original author, parallel cases, drawn mainly from American experience, have been added by the translator, which, even if they do not appeal specially to the English reader, at any rate make the illustrations fuller. Much new matter has also been added to bring the book up to date, together with plentiful references to English papers on the subject.

All this adds greatly to the value of the book, but best of all, the translation has been done into excellent English, so that involved confusion that appears inseparable from German prose composition is converted into a clearness of expression almost French in its style. The number of full stops has been, we should think, at least doubled, and the commas proportionately reduced in number, characteristics which make the reading a pleasant contrast to the general run of translations from German authors.

May we express a hope that Professor Ward may see his way to giving us a work on North American climatology; as encyclopœdic as are the publications of the American Weather Bureau, the very completeness of the work of that model national institution making it extremely difficult for Englishmen (we refuse to say foreigners) to gain any clear idea of the climatic characteristics of the vast area with which it deals.

A Handbook of Climatic Treatment, including Balneology. By W. R. Huggard, M.A., M.D., F.R.C.P. London: Macmillan and Co., 1906.

There are probably no specialists who more frequently require to prescribe "change of air" than those who deal with tropical diseases, whether while acquiring a hard-bought experience abroad, or when in after years the returned Tropical physician is sought out by the returned layman. Those still practising in the Tropics are continually meeting with cases in which change is not merely "indicated," but is an absolute matter of life or death; and the puzzle always is, where to send them. As a rule, the practitioner is content simply to get a patient out of the Tropics by the shortest route, with the result that he makes straight for his native place—perhaps Edinburgh in March—and is rewarded by a severer and more prolonged bout of malarial fever than he has had to endure in his entire tropical experience. The tropical practitioner's library must needs be select, if not absolutely scanty, and if it contain no work on health resorts he is hardly to be blamed; as it must be confessed that a large proportion of so-called balneological literature savours too strongly of the patent medicine vendor, the reader finding that the vaunted locality is "contraindicated" only in ingrown toenail and the acute stage of bubonic plague.

The work under review, however, concerns itself mainly with general principles, and is entirely free from pretentious matter of the sort alluded to, so that we feel sure it will be most useful to those who require a convenient epitome of climatic treatment, and to none less than the tropical practitioner.

We say this, albeit tropical maladies are scarce mentioned in its pages, and the word malaria does not occur in the index, although there is a casual mention that malarial convalescents do well at Davos, a fact well known to most tropical specialists, with the reservation, of course, that they must be re-acclimatised in some moderately warm, dry climate before they can be considered fit for so tonic and bracing an environment.

It speaks highly, too, of the book, that even in the case of the author's own station of Davos, the contra-indications are numerous and evidently the outcome of thoughtful experience.

Of the 520 pages to which the work runs, the first 60 are devoted to meteorology from the general point of view, and we are least pleased with this portion of the work, as it occasionally lacks the clearness of the rest of the book; some of the explanations being rather hard to follow, even to one fairly conversant with the subject. To our thinking, the space devoted to the subject, while far too short for exhaustive treatment, is too long for an outline, and there are occasional errors, as, for example, the explanation of the comparative coldness of the upper layers of the atmosphere, which is said to be "mainly due to the physical law of the expansion of gases." Now this law explains only the rather exceptional case of the coldness of up-hill winds, but the absorption of heat from expansion under these circumstances would rapidly be replaced by the sun's rays; were it not for the true reason, which is the universal operation of the law of selective absorption. Air, whether dry or wet, is very transparent to short-wave rays, but absorbs the long dark heat waves, such as are radiated by the ground, and therefore acts in the same way as the glass of a greenhouse, forming a sort of heat-trap. The more dense the atmosphere, the more efficient it is in this respect, and hence naturally the rarer upper regions, being less efficient heat-traps, do not trap as much heat.

Moist air is a much better trap than dry air, but this does not affect the explanation, as under any circumstances the upper layers would be to a greater or less extent cooler. In a book devoted mainly to the sanitary aspects of meteorology we should have expected better information as to the composition and effects of town fogs, but the subject is dismissed with a mere casual mention, and F. A. Russell's researches on London smoke deposits are not even noticed. Speaking generally, indeed, the bibliography of the subject is most scantily treated, so that the book affords but a poor guide to those whose interest having been aroused, would wish to follow up some point further. The construction in these chapters, too, is often loose; on page 47, *e.g.*, we are told that "the black bulb registered 55·5° C., while at the same time the temperature of the snow in the shade was 5·5° C." We presume the air over the snow is meant, for at 5·5° C. the snow, of course, would become water. Again, we are told at page 211 not to put faith in meteorological tables, when the author merely intends to caution us against comparing tables that, owing to varying hours of observation, &c., are in no way comparable; for he evidently very properly regards meteorological data as the only sound source of information. Still, such tables are rather wanting, and he cannot help wishing that the greater portion of the first 60 pages had been devoted to terse tabular statements of

monthly climatic data in connection with the various health resorts discussed. Other instances might be given, but we are not concerned in picking holes in a really meritorious piece of work, which can be thoroughly recommended to those who require a handy reference book of the subject.

PROFESSOR DAVIS ON THE EFFECTS OF ARIDITY.

THE current number of the *Geographical Journal* includes a paper on "The Geographical Cycle in an Arid Climate," by Professor W. M. Davis, which will be read with especial interest by all whose work has led them to such ill-favoured regions. The "geographical cycle is the period in which an uplifted land area will, if no disturbance occur, be worn down to base line by the processes of erosion." The absolute duration of such a cycle, therefore, varies enormously in proportion to the activity of the erosive forces, and tends to be indefinitely prolonged under conditions of aridity, where denudation by rain is insignificant, and the effects of wind only tend to predominate. The characteristics of the resulting desert landscape are broadly indicated, and will afford interesting food for reflection to those who have opportunities of visiting such scenes.

PROFESSOR KOCH'S WORK IN EAST AFRICA.

THE current number of the *British Medical Journal* contains a good abstract of Professor Koch's preliminary statement of his work in East Africa. The subject is, however, far too important to the special class of students of Tropical Medicine to be dealt with in this way in our pages. Its translation *in extenso*, and the reproduction of the numerous illustrations, are in progress, but necessarily take some little time to carry out. We hope, however, to be able to provide our readers with the paper in English dress in the first issue of the month of February.

SCORPION POISON.

So little is known about scorpion poison that it is satisfactory to find that the subject is being taken up by MM. C. Nicolle and Catouillard, who have been experimenting on the poison of the common North African species, *Heterometrus maurus* (*C. R. Soc. de Biologi*, 1905, pp. 100-102). So far their experiments do not seem to promise well for the discovery of either an antidote or a protective serum, as small doses conferred no immunity on rabbits. Antivenomous (snake) serum also has no protective action, though this could hardly be expected, as scorpion poison does not appear to resemble any form of snake poison.

At the same time, there must be some method of producing immunity, as all who have been in the East know that certain individuals, usually fakirs, obtain a curious power of handling these animals, and will allow themselves to be stung without suffering any apparent inconvenience. G. M. G.

NOTES FROM ANGOLA.

By F. C. Wellman, M.D.

Corresp. Memb. Am. Soc. Trop. Med.

(*Concluded from p.* 345.)

Note XIX.—The Occurrence of an Embryo Intestinal Worm in the Blood Stream and its Conceivable Import.

The worm seen by me in the blood of an Angolan negress, and described in the Journal for February 15th, 1904, has been pronounced the larva of an intestinal parasite. Looss' discovery that larvæ of *Uncinaria duodenalis*, after piercing the skin, leave the subcutaneous tissue in the blood stream, and, passing through the right heart to the lungs, travel up the trachea and down the œsophagus to the stomach and intestines, has suggested to me that my worm may possibly be the larval form of some other intestinal parasite which, when observed, was in the process of reaching, by a similar route, its normal habitat in the alimentary canal. It may turn out that several forms of helminthiasis can be prevented by cleanliness of the skin.

Note XX.—On the Possible Heterogenesis of Auchmeromyia luteola, Fabr.

While engaged in working out the complete life-cycle of *A. luteola*, I was recently told by the blacks that its larvæ were capable of both sucking blood like a tick and also of embedding themselves in the skin. Further enquiry was rewarded by the appearance of a native with a small swelling in his side, from which I extracted a maggot identical (in size, shape and, so far as I could see, every detail, including the mouth parts) with the usual hæmophagous larva of *A. luteola*, so common in this region. I have since looked for, but hitherto failed to find, more than this single instance. It would be interesting should these anomalous blood-sucking maggots prove to be capable under certain circumstances (possibly when the skin is slightly broken from any cause) of causing, like their allies the larvæ of *A. depressa*, ordinary cutaneous myiasis in addition to their equally disgusting *role* as vermin.

Note XXI.—Quartan Malaria in Tropical Africa.

The writer for some time thought that probably the malignant parasite was the only form of malaria to be found in this region. During 1904, however, one case showing the quartan parasite was seen in Biké district, and during the past year (1905) several unmistakable cases of the latter infection were studied in Bailundo district. The type differs in no respect that I can detect from that seen in quartan cases in other countries. The infection cannot be recognised clinically, however, for in only one case was there slight irregular fever, while three other cases in which the parasite was plentiful and regularly going on with its cycle showed no symptoms whatever. Probably native Africans who have become practically immune to the effects of *Hæmomenas præcox* are as a rule undisturbed by this feebler variety which at home sets up a very respectable fever. Out of a series of 531 natives recently examined by Mr. W. E. Fay and myself, 14 individuals showed the quartan parasite in their blood. Benign tertian has not yet been seen.

Note XXII.—Intoxicating Drinks, Drug Habits, &c., in West Africa, and their Relation to Mental Disease.

The following remarks refer only to the Angola Bantus' :—

Alcohol.—They constantly use and occasionally get very drunk on their native beverages, principally maize beer ("ochimbombo"), and a mead made of honey and water ("ochasa"). Palm toddy ("alufu") is also drunk in some districts. Of late years the Portuguese, having ignored their agreement not to introduce rum among new tribes, that beverage has become common right into the interior.

Tobacco.—Universally used, generally in the form of snuff, but not seldom smoked; it is never chewed.

Hashish (*Cannabis sativa*) is smoked by a certain per centage of the natives; more common in some districts than in others.

Kola (*Sterculia acuminata*) is extensively used in some localities north of the Coanza River, so much so that there is a superstition among the blacks and Creoles that one cannot endure the climate without it, which is expressed in a rhyming proverb which may be roughly "Englished" in this fashion—

"Who doesn't eat Kola
Can't live in Angola."

"*Okapilangau*" (*Burkea africana*).—The bark is chewed, and also occasionally inserted into the vagina by women as an aphrodisiac.

Mental disease is very rare among these people. Rum and hashish are the most deleterious stimulants used by them. I have heard the statement made that hashish smoking is a frequent cause of insanity among them. Such statements lack proof. Of the few cases of mental derangement I have examined none were hashish smokers.

Note XXIII.—A Suggestion as to the Probable Relation of Chiggers to Ainhum.

I have recently pointed out on two occasions the possibility of chiggers bearing an etiological relation to ainhum. I have long noticed that the chigger has, even in healthy feet, a predilection for the under-surface of the little toe. When the skin of this region is, as is so often the case, cut or torn, the liability to invasion is increased, for one of the first things that one notices in regard to the chigger's habits is that it enters abraded or irritated surfaces oftener than sound skin. The inevitable inflammation and cicatrisation following such invasion accounts for at least part of the symptoms belonging to ainhum. I have stated this hypothesis more in detail elsewhere in a paper from which I here quote: "The fold of skin under the proximal joint of the little toe corresponding to the edge of the web between the toes is the point where wounds are oftenest made by the sharp grasses, &c., through which the barefooted native walks and runs.

The principal reason for this in the African is that the little toe of barefooted negroes lies separate from the others at an angle due to anatomical reasons connected with flat-footedness. As I have said, chiggers are oftenest found on the under-surface of this toe, even when all the toes are intact. When wounds are once made here, however, the chiggers persistently invade them, and must be removed constantly. While I do not wish to be read as advocating *S. penetrans* as the sole cause of ainhum, it seems to me that this insect must play a part (in some instances at least) in the continued irritation which, especially in blacks (who have a fibrogenetic tendency), may lead to the contracting fibroses occasionally resulting in the spontaneous amputation known as ainhum. It may be further stated that such a theory goes far to account for the geographical distribution of the disease, which is particularly common in the two great homes of the chigger, viz., tropical America and Africa."

Note XXIV.—The Influence of Various Plants on the Habits of Mosquitoes.

On referring to my diary I find, scattered over two or three years, the following notes of experiments as to the effects of different plants on the actions of mosquitoes. In each case the test was not whether the mosquitoes would come to the plant in question, but whether the plant tested would drive the mosquitoes away when placed in one end of the cage containing them. As many substances such as wormwood, tobacco, chrysanthemum, pyrethrum, &c., when burned (and also various volatile bodies, viz., essential oils and various gases) will do this, it would not seem an unreasonable test. The mosquitoes experimented upon were principally of four species common here—*Culex hirsutipalpis*, *Heptaphlebomyia simplex*, *Myzomyia funesta*, and *Pyretophorus austeni*.

Castor-oil plants (*Ricinis communis*). No effect whatever. Both Anophelines and Culicines alight on the leaves quite as often as on banana leaves used for comparison.

Gum trees (*Eucalyptus globulus*). No effect unless the leaves are crushed, when the gnats seem to avoid them.

Pawpaw (*Papaya vulgaris*). No effect.

Sunflowers (*Helianthus sps.*). No effect.

On the other hand, large plants, when cultivated near quarters, afford shade (and even breeding places), and so actually increase the number of mosquitoes. The principal plants here which afford collections of water suitable for breeding mosquitoes are: a bamboo (*ombungu*), bananas (*ahondio*), metroxylon (*etome*) and especially two *Bromeliaceæ*, *Amomum sp.* and *Costus sp.* (*ovomoma* and *ochiteke*). Some of these are cultivated as useful or ornamental plants. I personally know nothing of the "neem," or margosa tree of India (*meliaceæ*), or of the vaunted effects of *Chenopodium vulvaria*, *Solanum nigrum*, and other similar plants, but, in view of my experience with African plants, doubt on general principles their reputed efficacy. In view of our knowledge of the mosquito's hatred of light and sunshine, the most obvious protection to a bungalow is a large surrounding open space kept free from depressions and clear of high grass.

Concluding Note.

In looking over these notes there occur to the writer other observations of interest which might have been added were the series not already so long. Some of these are: The effects of the venom of the puff adder (*Clotho arietans*), Additional Notes on the Mosquitoes of Bihé, Dental Caries among the Angola Blacks, Cutaneous Diseases, Venereal Affections and Eye Troubles in Angola, Tumours and Cancer in South-west Africa, the Climate of the Interior of Benguella, Reports on Various Collections of Entozoa, Noxious Arthropods, &c., &c. Several of these have, however, already been published in more elaborate papers and reports. The foregoing notes have served as a sort of clearing-house for some of the many scattering memoranda which collect in one's medical diary during the course of study and practice, and remain after the notes bearing on special investigations in hand have been transferred. If, therefore, I add to the observations contained in the preceding notes a list of the diseases not therein mentioned which I have reported from South Angola, the reader interested in the geographical distribution of tropical disease will be able to compare the district with other regions. These diseases are: Subtertian Malaria, Filariasis (*F. perstans*), Ankylostomiasis, Cestode Infection, *Oxyuris vermicularis*, *Trichocephalus dispar*, Bilharziasis, "Vonulo" (*Sternodynia neuralis endemica*), Leprosy, Ringworms, Prickly Heat, Leucodermia, "Craw-Craw" (severe scabies), Beri-beri, Low Fever, Heat Stroke, "Akatama" (*Neuritis peripheralis endemica*), Manioc Poisoning, Poisoning by Witch Doctors, "Onyalai" (hæmorrhagic bulla), Marginal Ulceration of the Gums, Keloids, Bites of Venomous Creatures, Milk-pox, Chicken-pox, Mumps, Epilepsy, Pneumonia, Spermatozemia, Gonorrhœa, Syphilis, Herniæ, Cancer and Tumours, Yaws, Blackwater Fever, Spirillosis ("tick fever"), Abscess of Spleen, Gundu, Ainhum, Climatic Buboes, Tropical Phagedæna, Myiasis, Multiple Nodules, &c., &c. New diseases and additional observations from this region which may be recorded from time to time will be published on some future occasion.

AN OUTLINE OF PLAGUE AS MET WITH IN BRITISH EAST AFRICA.

By James A. Haran, M.A., M.B., B.Ch.(Dublin).
Medical Officer, Mombasa, British East Africa.

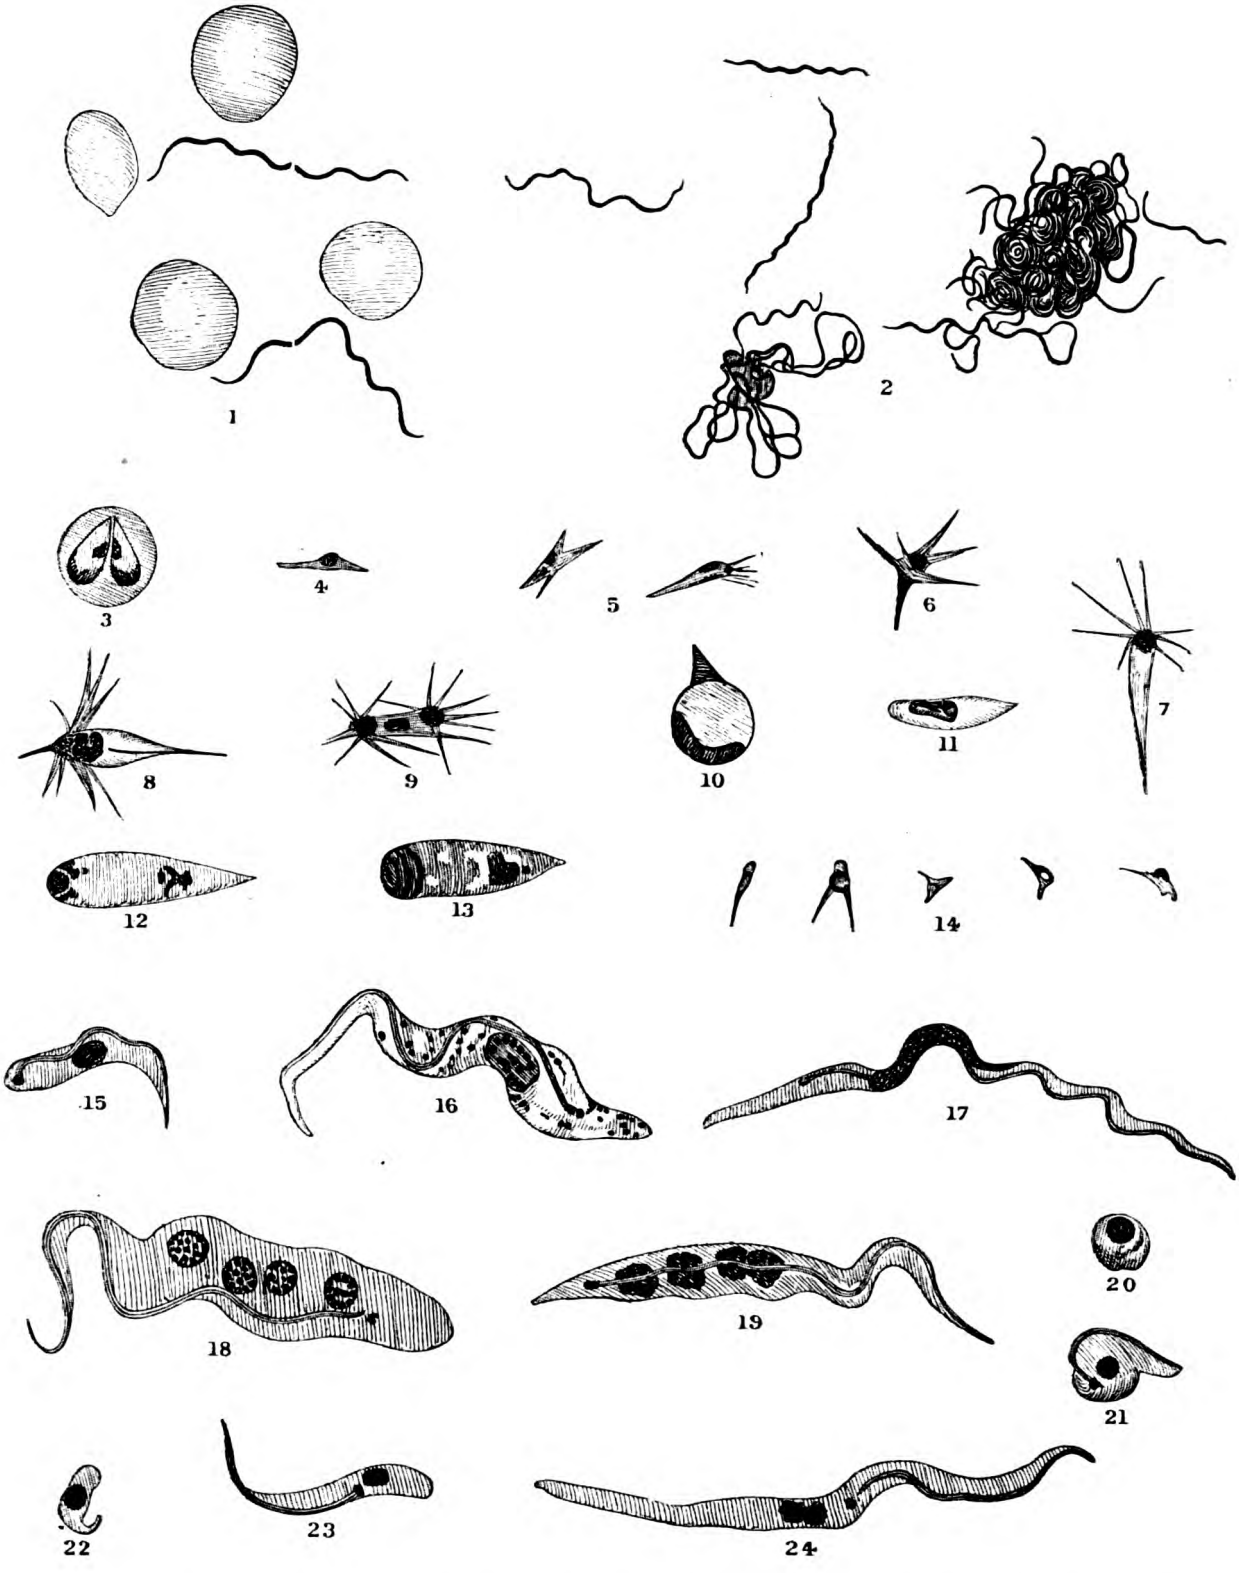
Plague is a specific infectious disease characterised by either—

(*a*) Local or general lymphatic tenderness and glandular enlargement.

(*b*) Septicæmia, associated or not with (*a*).

(*c*) Pulmonary or intestinal manifestations of a rapidly fatal character.

Previous to the establishment of European government, native tradition records two outbreaks, one among the Wateita, whose territory is about 100 miles from the coast, and the other among the section of Wakanionda dwelling on that part of the shores of the Victoria Nyanza now occupied by the terminus of the Uganda Railway. The latter people preserve a



To illustrate "Preliminary Statement on the Results of a Voyage of Investigation to East Africa." By R. Koch.

very lively remembrance of the outbreak, inasmuch as the disease dislodged them from place to place for a period of years, and was accompanied by a fatal disease affecting their cattle. The neighbouring kingdom of Uganda has been frequently visited by localised outbreaks, and is known to the natives as "Kaumpuli."

Since the establishment of the Protectorate five outbreaks have been noted, two of which were preceded and accompanied by the wholesale death of rats. Three of these took place at stations on the Nyanza, and two at Nairobi, a headquarters station 326 miles from the coast, and 5,800 feet above sea-level.

The *Bacillus pestis*, the exciting cause of the disease, is a non-motile, non-sporing, aerobic organism with rounded ends, 1·5 μ in length, stained by ordinary dyes, and decolourised by Gram. The colouration is best marked at the poles, the central area being left unstained. It is of low vitality, and easily destroyed by sunlight. The usual procedure for its demonstration is the introduction, with the usual precautions, of an exploring needle into the enlarged gland or bubo of the patient. The piston is then slightly withdrawn and the needle removed, the unstained fluid being ejected and spread on a slide. The puncture is covered with antiseptic dressing.

Leishman's is a useful and ready stain with which to treat the film. A pure culture is usually demonstrated. The sputum in the pneumonic form affords material for excellent smear preparations. In rats and cats the bacillus can be detected by means of smear preparations made from sections of the submaxillary glands and the spleen. In dead bodies smear preparations can be made from the particular organs found to be affected.

I am inclined to think that puncture by an exploratory needle of a plague bubo in a living patient is not altogether a harmless proceeding, inasmuch as it allows additional infective material to enter the blood stream, as well as injuring a gland or mass of glands engaged in opposing the entrance of infection. In doubtful and mild cases it is very useful for purposes of diagnosis.

The bacillus has been demonstrated twelve times after death. In some cases the staining reaction was not well marked, while in others a bulbous enlargement was observed at one or both poles.

The disease is usually conveyed by—

(*a*) Infected rats.

(*b*) The discharges of patients.

(*c*) Infected food.

When a community of rats is invaded by the disease those which are unaffected emigrate in a body from the area, to return at a later period. At the commencement of the outbreak in Kisumer during the present year a European who was camped some distance outside the settlement was surprised one night to find his tent invaded by swarms of rats passing through, apparently in a hurry and from the direction of the town. He had no further visits, and a few days later the first cases were discovered.

The diseased rats emerge from their burrows and stagger about in the open, passing large quantities of infective dung. It is easy to understand that individuals walking on this material with bare, abraded, and cut feet, collecting the sweepings of the floor with injured hands, or not washing their hands subsequently, and using them (as natives will) instead of a suspensory bandage, are liable to contract the disease. I happened on a case in which a Beluchi slept on the floor of an infected house with an abraded ear, and was subsequently brought into hospital with a cervical bubo. In another instance a boy was secretly ordered to sweep the floor of an infected house, with the result that he was dead the next afternoon of pneumonic plague, presumably caused by inhalation of the dust. As a native eats with the hand direct there is also danger of food contamination.

The discharges of patients are especially dangerous in the pulmonary form of the disease.

The bubonic variety does not apparently possess such grave terrors. We had one case of an Indian child with an axillary bubo, who was attended by a servant of his own caste. This latter was supposed to sleep close at hand on a rug, but I frequently caught him sleeping in the same bed. He never developed the disease. The discharge from suppurating buboes has been frequently examined, but most usually no bacilli have been demonstrated.

Clothes soiled by discharges, after exposure for some time to the sun, would seem to be harmless, if one is to credit the records of the Egyptian outbreaks of the commencement of the last century. Among them one finds it stated that the wearing apparel of the dead were hawked through the streets, and that they were subsequently worn by their buyers with impunity.

Food is liable to be contaminated by the discharges of infected rats, which are found dead or dying among bags of grain, &c., or by the dust of infected areas. Consumption of such may give rise to the bubonic form, involving the submaxillary glands, or to the intestinal form. Predisposing causes may be summed up as insanitary habits and defective houses. The barefooted and poorly fed Asiatic, who insists on excluding all possible light and air, whose ablutions are nominal, and who prefers to dig a latrine in the floor of his bedroom rather than go outside, can hardly be accused of possessing powers of resistance to disease. The structure, moreover, of his house leaves much to be desired. It usually consists of an earthen plinth, faced with mud and stone, on which is built a galvanised iron shop and dwelling place combined. Windows and ventilation are avoided, if possible. Within, as much merchandise is placed as can well be stored, his bed being almost surrounded by bales. Unless for sale purposes these are never shifted, so that a practically permanent home is afforded to the rats. Thus, on an outbreak taking place among these rodents, evidence is concealed for some time.

Clinical Course.

The incubation period varies between twelve hours and seven days. I have been unable to ascertain the presence of any signs or symptoms during that period, such being, perhaps, due to a desire for concealment on the part of the patient when brought to hospital, or to mental torpor resulting from the infection and consequent inability to answer questions coherently. The invasion is sudden and characterised

by intense headache, vomiting, sometimes diarrhœa, epistaxis, furred tongue, and a rise of temperature to between 102° and 104° F. The respirations vary between 30 to 40, the pulse between 130 to 145, being small and compressible. The gait is staggering and the voice thickened. The face is pale and characterised by an expression of fear. The conjunctivæ are injected. In the bubonic form the appearance of a bubo may be simultaneous with these signs or may follow within forty-eight hours. The commonest situation is in the femoral region. They may also be found in the axillary, post-cervical, transverse inguinal, or lumbar groups, or involving one or more of the submaxillary glands. General gland enlargement is occasionally met with. Tenderness along the course of the lymphatics is always present, as well as in the regions of apparently unenlarged glands. The bubo consists of a conglomeration of inflamed glands. It may not be larger than the terminal phalanx of the little finger and may remain so during the course of the disease. On the other hand, it may gradually enlarge and, before death, present a tumour as large as the closed fist. It is granular, hard, intensely tender on palpation, and is surrounded by a large area of infiltrated cellular tissue. Movement is avoided, as it causes exquisite pain. Incision at this stage liberates a small quantity of bloody serum which, under the microscope, shows a pure culture of the *B. pestis*. As the disease progresses the bubo usually enlarges and the general symptoms become more severe, temperature varying between 103° to 104°, respirations 40 to 60, pulse 145 to 160. The voice becomes incoherent and the patient unable to stand. The tongue is dry, brown in the centre, and red at the tip and edges. Secondary buboes appear, *e.g.*, in femoral manifestations, the iliac group, axillary, the infra-cervical. The area of periglandular infiltration increases. In the femoral region it forms a large triangle with the base resting on Poupart's ligament. In the axilla the swelling extends from the inner wall up to and above the clavicle, and may cause œdema of the arm. In involvement of the submaxillary glands the lower part of the face, on the affected side particularly, is so swollen as to render the patient almost unrecognisable. All the above changes may take place within forty-eight hours. Secondary pneumonia of fatal import sometimes appears, causing hæmoptysis, and pain and tenderness over the affected area, with fine crepitation on auscultation, the expectorated blood being full of bacilli. Between the third and sixth days in the bubonic form cases usually die. Should the patient survive and the bubo go on to suppuration, bogginess and redness appear over the infiltrated mass about the sixth day, followed by fluctuation on the eighth and twelfth day. On opening the abscess the general symptoms at once disappear, the temperature falling to between 96° and 97° F. morning and evening, the pulse below 70, and respirations 14. The tongue clears and the abscess cavity rapidly fills up. At this period a pseudo-dysentery, with tenderness over the colon, is very frequently observed, and is probably due to elimination of the toxin. During the healing of the wound the infiltration gradually lessens and the glands slowly reappear from the mass. A certain amount of thickening and gland enlargement persist up to at least three months and probably for some years.

In favourable cases not ending in suppuration, the termination of the disease is reached more slowly, subsiding masses of glands remaining tender for a long period, and liable, on slight or non-appreciable causes, to become enlarged again. Rises of temperature, associated with delirium, may accompany these manifestations. Pseudo-dysentery has been also noticed at the conclusion of these cases.

In fatal cases of *the bubonic variety* the general symptoms and signs become aggravated, the temperature falling to 100° or 101°, respirations exceeding 60, pulse uncountable. Râles are found on auscultation over the pulmonary area. Restlessness and subsultus appear. Involuntary evacution of bladder and rectum may take place. Bubonic tenderness persists to the end. With all this the patient may preserve some degree of consciousness to the end, which is caused by failure of the cardiac centre, resulting from toxæmia. One case, that of an Indian babu, was in my charge, who insisted on lighting a cheroot. I went outside for a moment, leaving him puffing with evident enjoyment. On my return within two minutes I found the man dead.

In the septicæmic variety, gland enlargement, usually general, with lymphatic tenderness, may or may not be present. The onset of the disease is sudden, the patient soon becoming delirious, with heightened colour, subconjunctival ecchymoses, and dry, brown tongue. Epistaxis appears early and sometimes continues, at intervals, during the course of the disease. Jaundice, with involuntary action of the bladder and rectum, quickly ensues. The spleen is enlarged and tender. Coma follows, and a fatal termination may be expected within three days of the onset of the disease. In this form of plague the pulse and respiration are even more rapid than in the preceding. The temperature runs the same course.

I have seen but one case of the *intestinal variety* It was that of a man resident in a quarantine camp with others for purposes of observation. They had been removed from some houses in which plague had broken out. The patient in question was suddenly taken ill about midnight with abdominal pain, vomiting, diarrhœa with hæmorrhage, and collapse. Constant evacuation continued during the night, but ceased with the advent of morning. Patient's temperature was 101° in the mouth, pulse 150, and respirations shallow and rapid, cutis anserina, and the tongue dry, furred and shrunken. A patch of bronchial breathing, with associated dulness and tenderness, appeared in the right apex and was accompanied by hæmoptysis. Patient died at one in the afternoon, the entire manifestation having lasted about thirteen hours.

The *pneumonic form* is the most fatal to the patient and dangerous to the attendants. In a case which came under observation the boy, an African, had been secretly engaged on the previous day to sweep out a house in the infected bazaar, which had been temporarily evacuated. The next morning the boy was awakened at four o'clock by a severe pain over the sternum and hypochondria, associated with dyspnœa. On being brought to hospital he could not

stand. He was lethargic, the voice was thickened and verging on incoherence, conjunctivæ suffused, temperature 103°, pulse 140, and respirations 60. On examination dry crepitations were found on auscultation over the bases of both lungs, with diminished resonance. Cough and expectoration were absent, as well as gland enlargement and tenderness. Two hours later the patient had passed into a state of torpor, the tongue being dry, black and shrunken, and lying in the bottom of the mouth. Bladder and rectum were acting involuntarily. Respiration was extremely rapid and shallow, and the pulse scarcely perceptible. He died at 1 p.m., the disease having run its course within nine hours. Infection in this case was due to inhalation of the dust.

Post-mortem appearances are: marked rigor mortis in association with well-marked putrefactive signs, submucous, subserous, or cavity hæmorrhages. Effusion into the various cavities, congestion or consolidation of pulmonary areas, pial congestion, enlarged spleen, tissue staining in the neighbourhood of vessels, enlarged masses of agglomerate glands, purple on section, the surrounding tissues being engorged with hæmorrhagic fluid. Intestinal congestion, the lumen being occupied by blood-stained fluid or actual blood casts. Heart chambers may be occupied by unformed clot.

Treatment should be of a stimulating character from the commencement. The early administration of brandy in frequent doses is often attended with good results. Digitalis and strychnine are also useful. The hypodermic infection of Yersin's serum is of the highest value. In the bubonic forms, belladonna and glycerine fomentations, or linseed meal applied locally, relieve the pain. I have seen improvement following on the hypodermic administration of morphia and strychnine. When fluctuation is palpable the pus should be liberated by free opening. Incision prior to the advent of suppuration is harmful. After evacuation daily dressing with pieces of cotton-wool saturated in 1-1,000 hydrarg. perchlor., may be applied and fixed by a bandage soaked in the same solution. I have never found drainage necessary. The cavity fills up quickly. Fluid diet is given in the earlier stages; solid diet may be resumed as soon as the bubo has been opened, should it suppurate, otherwise the special circumstances of each case have to be studied. I have seen patients given solid diet through the entire course of the disease. In the intestinal form stimulants and astringents should be administered vigorously, very little time, however, is available. It is possible that Yersin's serum in large doses would be of advantage, but the great exhaustion which quickly follows the onset of the disease should not be forgotten.

The pneumonic form is practically hopeless as regards treatment. Stimulants and Yersin's serum may be administered freely. The septicæmic variety may be treated on similar lines. Isolation is essential in the septicæmic, intestinal and pneumonic forms, more especially in the last. The medical attendant should make his examination in the open air, if possible. Should the patient be expectorating aimlessly in every direction, the wearing of some form of face protection is to be recommended. In its absence I should be disposed to cover the patient's face with a towel, which might subsequently be boiled. A drawback to such procedure may be the possible irritation on the patient's part. In such eventuality a lot may be taken for granted. When it is considered that the subjects of suppurating buboes (which result from a mixed infection) frequently recover, should they survive the earlier days of the disease, it might be useful were experiments made in the administration of measured doses of toxin, derived from pyogenic cocci, to animals inoculated with plague. There would seem to be an antagonism between the former and the *B. pestis*.

Prophylaxis.

Cleanliness, light and air, rat-proof houses, and the destruction of these rodents, are essential. An outbreak of plague rarely reaches large proportions, unless the rats are involved. Experiments are in progress with a view to obtaining a germ capable of causing their wholesale destruction. The Danysz bacillus has been successful with mice, and it is to be hoped will prove equally so with rats. When a case occurs in a house the patient should be removed to hospital and the other residents placed in an isolated building or camp under observation. Persons wearing boots should then enter the house and first lay the dust by freely sprinkling the floor with a solution of Jeyes' crude carbolic or other antiseptic. The goods and furniture are then taken out and placed in the sun, all rubbish or uncleanly material being destroyed or disinfected. Additional windows may be made, if thought necessary, and they, together with all doors, should be left open. The walls are then covered with limewash, and the floors sprinkled freely with lime, or saturated with strong carbolic or corrosive sublimate solution. Haffkine's prophylactic may be administered to those isolated for observation. This is usually injected in varying doses and with antiseptic precautions into the outer side of the arm. Within twelve hours reaction occurs, accompanied by rise of temperature, and pain, tenderness and enlargement of the corresponding axillary glands. The temperature quickly subsides, but the gland phenomena persist for about a fortnight.

Inoculation gives rise at first to an increased susceptibility to infection, followed in a week or so by an immunity, which persists for a fortnight or three weeks. The advantage of the measure is that it replaces to a certain extent the more cumbrous practice of quarantine. Despite the above, plague may persist, the rats continuing to die. When these are involved the length and extent of an outbreak probably depend on the time the disease takes to work through the affected rat community and the extent of country over which that community ramifies. When cleanliness and general precautions have failed we have caused the evacuation of the infected area, placing the inhabitants in tents. This is a costly proceeding and only possible in small settlements. Were one certain of the guard and the weather, it might suffice to sleep in the streets, leaving all doors and windows of the houses open. This remark, of course, applies to tropical countries.

In endemic areas it is possible that the disease constantly exists among the rats in a very mild form, and that increase in their numbers or aggregation in

human habitations causes an aggravation of the type and consequent communicability. It might be of interest to hold enquiry into all lymphatic manifestations occurring among the inhabitants of an endemic area, as it may not be impossible that the disease is constantly present in a mild form and passes unobserved.

AN OUTBREAK OF ACUTE CONTAGIOUS CONJUNCTIVITIS IN CEYLON.

By Sir Allen Perry, M.D., D.P.H.,
Principal Civil Medical Officer; and
Aldo Castellani, M.D.

In March of last year our attention was drawn to several cases of the above disease which occurred in the city of Colombo, and our thanks are due to Dr. W. H. de Silva, the Ophthalmic Surgeon of the General Hospital, for his courtesy in placing at our disposal the clinical material for the preparation of this paper.

In our experience such an outbreak had not been seen previously, and we have the authority of Ceylon practitioners of longer experience of eye diseases in the island than ourselves, who state they do not remember a similar occurrence.

The first cases were thought to be examples of gonorrhœal conjunctivitis until a bacteriological examination of the secretion demonstrated the error. As a noticeable characteristic the outbreak was limited practically to the well-to-do classes, there were more Europeans attacked than those of any other race, and it was almost unknown among the poor. The onset of the disease was sudden, with early symptoms of an alarming nature, and its course was rapid. It yielded readily to treatment, and serious complications were rare.

During the prevalence of the north-east monsoon in the early months of the year the meteorological conditions over the western part of Ceylon are high temperature, low humidity, a long spell of drought, and uninterrupted brilliant sunshine. These conditions seem to favour the development of a small fly, one of the family *Muscidæ*, popularly known as the "eye fly," from its habit of always trying to settle on that organ.

At this season of the year the surface of the roads is pulverised by the traffic into an irritating red dust, which is blown about by the wind in clouds, and it is usual to come across many cases of simple catarrhal conjunctivitis in all classes, particularly among the prisoners in the gaols. The cause of this affection is commonly attributed to the dissemination of infective particles by one or other, or by both, of the above-mentioned effects of the meteorological state. No history of the introduction of acute contagious conjunctivitis could be traced, but the probability of this is great, considering the large number of ships that arrive at the port daily, bringing foreigners from all parts of the world. The symptoms of this outbreak were an acute onset with great swelling and discolouration of the eyelids, an early watery discharge becoming muco-purulent and in some cases purulent, swelling of the conjunctiva, especially of its ocular portion, with subconjunctival hæmorrhages (the hæmorrhagic catarrhal conjunctivitis of Nettleship), and photophobia with pain of a burning character.

The cases were extremely infectious, more than one member of the same family being attacked.

In many instances both eyes were affected. We consider the incubation period was from twenty-four to forty-eight hours.

The ages of the patients ranged from two years to forty years, the greater number were in children and young adults. An attack lasted about three weeks, and as a rule there were no complications. Haziness of the cornea occurred in a few cases, and in only one of them was there any permanent corneal damage. This case is so interesting that we give it some detail.

The patient, a planter's daughter, 2½ years of age, living in a remote part of the country, had been suffering from the affection in both eyes for about a week before she came to Colombo. When seen by us she had great swelling of the lids, blepharospasm, a purulent discharge, and an ulcer on the lower segment of each cornea, with a bound-down pupil on the left side. In the experience of one of us the destruction of corneal tissue in cases of gonorrhœal conjunctivitis generally occurs in the lower segment of the cornea; the reason for this determination of site is the extra pressure there, produced by the overlapping of the upper lid; these conditions were present in this particular instance.

The ulcer on the right side and the general condition of that eye yielded rapidly to treatment, but the corneal complication of the left eye increased in depth and area, notwithstanding the application of pure carbolic acid and subsequently the actual cautery. After some days the destructive process stopped and the ulcer was seen to be filled by a yellowish-grey membrane, the surface of which was glistening and level with the rest of the cornea. This membrane was easily peeled off, leaving a clean, ragged bed; a fresh layer formed within twenty-four hours after each time it was removed. The membrane was examined by one of us for the Klebs-Loeffler bacillus with a negative result. This pseudo-membrane may have been the result of the caustics, or more likely it was an instance of the development of an exudation which is said by Weeks to happen in 4 per cent. of cases of acute contagious conjunctivitis. The formation of the pseudo-membrane continued for about a month and the child made a fair recovery, but with a scar which is likely to be permanent.

Bacteriological Examination of the Cases.—We have examined microscopically and bacteriologically the secretion from six patients.

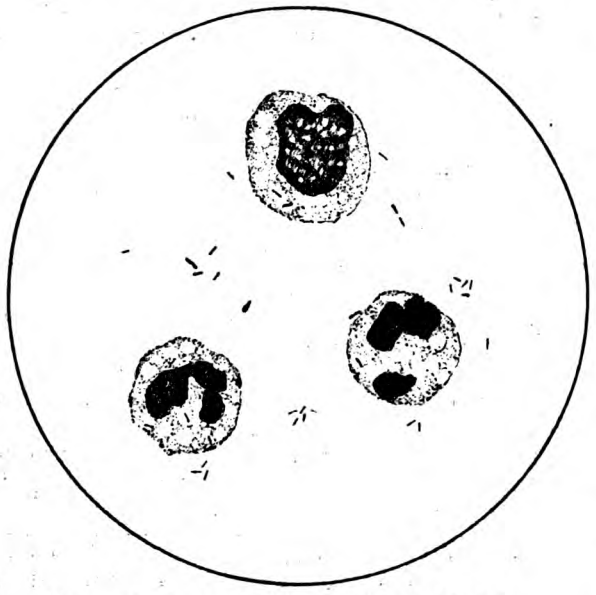
Fresh and stained preparations were made. The discharge consisted of numerous leucocytes, most of which were polymorphonuclear; some fibrinous threads and a few squamous epithelial cells; occasionally some erythrocytes could be seen. In fresh preparations, using a high power and a very small diaphragm, some short, slender non-motile rods could be detected.

Films stained with the usual aniline dyes showed fairly numerous bacilli. The stain which brought them

out best was diluted carbol-fuchsin (1 in 20), which was allowed to act for ten minutes. These bacilli appeared as short, thin, straight rods, evenly stained throughout their length, which varied from one to two microns; no capsule was present.

The organisms were often grouped together irregularly; in rare instances some were arranged in short chains. Many were contained in the protoplasm of the leucocytes.

The bacilli were decolourised by Gram's method. These morphological characters suggested to us at once the probability of our being in the presence of the Koch-Weeks bacillus, which proved to be the case by



Preparation stained with diluted carbol-fuchsin.

the results of the cultural investigation. We employed the ordinary laboratory media, as well as blood agar prepared by smearing on the surface of the agar tubes some drops of blood taken aseptically from the finger; the media were inoculated with the purulent discharge under aseptic precautions. In the first case examined all media, including those containing blood, remained sterile, with the exception of one agar tube, which showed three or four colonies of the *Micrococcus pyogenes albus*.

In the remaining five cases the blood agar medium, kept at a temperature of 35° C., showed after thirty to forty-eight hours some growth; and of the other media some remained sterile, while others showed a few colonies of staphylococci. The blood agar tubes presented small, roundish, translucent, *dew-like* colonies, with very little tendency to become larger or confluent. Preparations from these showed small non-motile bacilli well stained by diluted carbol-fuchsin and not stained by Gram's method. We succeeded in obtaining subcultures from these colonies on blood agar, while we always failed with the ordinary media. The organism showed a great tendency to die out rapidly.

The morphological and cultural characters described clearly show that the germ isolated by us was the typical Koch-Weeks bacillus (*Bacterium ægyptiacum*, Lehmann and Newman). We must add that in one case (Case No. VI) we found associated with it a bacillus of the xerosis group. On the blood agar tubes in this case, besides the typical colonies of the Koch-Weeks bacillus, there were larger, opaque, granular colonies easily distinguishable. Preparations from these colonies showed bacilli which were well stained by Gram's method. To this association of the xerosis bacillus with the Koch-Weeks, we are not inclined to place much importance, as it is well known that the xerosis bacillus can be found very frequently in any inflammation of the conjunctiva.

Pathogenicity of the Koch-Weeks bacillus isolated in Ceylon.—We have made several attempts to infect animals. We give here a few examples of our experiments.

Experiment 1. *Monkey.*—Into the conjunctival sac of the left eye were instilled three drops of the purulent discharge containing many Koch-Weeks bacilli collected from Case No. IV. Result: *Nil*; not even the slightest hyperæmia was noted.

Experiment 2. *Monkey.*—In the conjunctival sac of the right eye an emulsion of two loopfuls of a blood agar culture of the Koch-Weeks bacillus was instilled drop by drop. Result: *Nil.*

Experiment 3. *Monkey.*—The conjunctiva of each eye was scarified by means of a sterilised pin. In the left conjunctival sac an emulsion in broth of one loopful of a blood agar culture was instilled. Result: Marked hyperæmia; the same degree of hyperæmia, however, was present in the other eye, where the scarification was not followed by the inoculation of the organism. In the inoculated eye the germ could be recovered during the first five hours, afterwards it disappeared completely.

Experiment 4.—The discharge taken directly from the patients' eyes, and in other cases emulsions of cultures, were injected into the conjunctivæ of several rabbits, guinea-pigs, and white mice. Result: *Nil.*

Experiment 5.—To study the virulence of the strains of the Koch-Weeks bacillus isolated by us, several guinea-pigs and rabbits were injected subcutaneously and into the peritoneum. All the animals survived without showing any signs of malaise. These researches on the pathogenicity of the Koch-Weeks bacillus found in Ceylon, gave the same results as have been arrived at in other countries, viz., that the germ is practically non-pathogenic for the lower animals.

"Clinical Studies," November 1, 1905.

Splenic Anæmia.

Bramwell, B., treated a case of splenomegaly with ferri carb., grs. v. thrice daily, and exposure of the splenic area once daily to X-rays. The spleen slightly diminished in size and the red blood count improved. In another case, boric acid in 20 grain doses in conjunction with quinine hydrobromate, grs. v., and tinct. ferri perchlor., min. x., allayed the febrile symptoms, and improved the general condition, but did not diminish the spleen. The temperature seems to have fallen in consequence of the exhibition of boric acid.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 „ „ 6/-;
200 „ „ 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 „ „ „ 11/-;
200 „ „ „ 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

FEBRUARY 1, 1906.

THE DEPRECIATION OF THE ATTRACTION OF THE INDIAN MEDICAL SERVICE AND ITS REMEDIES.

I.

No body of medical men have done more to advance our knowledge of tropical maladies than the officers of this ancient and honourable service, and its welfare is therefore of great public importance. In the early days contributions by practitioners in the Tropics to medical literature were evidently regarded by their brethren at home almost in the light of travellers' tales, or at any rate of no more than a curious interest to the general body of the profession. The establishment of tropical medicine as a distinct branch of the healing art may, indeed, be said to date from the establishment of a chair on the subject at Netley, to which a retired Indian medical officer, the late Professor Maclean, was appointed. Maclean was a man of exceptional ability, as well as a born lecture-room orator, and his lectures and valuable systematic work on the subject soon elevated tropical medicine to a recognised position in the medical commonwealth. He taught, amongst other forecastings of modern opinion, the value of the mosquito net in the prevention of malaria and the communicability of cholera through the agency of water; though it must be confessed that it never seems to have occurred to him that the efficacy of the mosquito net might be due to its efficiency in excluding mosquitoes.

From the therapeutic side, however, his book may to this day be consulted with the greatest advantage, and it is a pity that no new edition has been prepared, as this side of the question has been a good deal neglected in the more modern works on the subject. About the early eighties the service seemed to be neglecting to maintain its reputation, though the work of Carter, of Bombay, on spirillum belongs to this period.

The burning question of the day was, however, the etiology of cholera, and the conflicting interests of the time led to unbiassed research being placed beneath the cold shadow of official disapproval. The Indian Government quite rightly regarded quarantine as useless, but unfortunately fell into the error of believing that its adoption depended, not on the question of its efficiency and expediency, but on that of the communicability or otherwise of the disease. When keen and scientific officers recorded facts tending to prove communicability they were accused of "theorising," and deliberately ordered to delete the facts from their official reports, so that a reputation for a weakness for research was about the worst a man could earn who desired to succeed in the service. The visit of Koch to India, however, tumbled the whole flimsy edifice based on the *supressio veri* about the ears of its authors, and what is more, demonstrated the inapplicability of quarantine; but the men who would have worked had packed away their microscopes in disgust, and it was some years before this blow to efficiency could be recovered from. The Indian Government had not, however, learned its lesson. It formally punished King, of Madras, for invaluable original work on the vaccine virus, and when Ross made his great discovery it first obstructed his work, and then, after according some tardy and grudging support, made no efforts whatever to retain the services of the brilliant investigator it found to its hand within the ranks of its own servants. Was there ever a better case for selective promotion?

There are signs, indeed, that matters are improving in regard to the promotion of research, but the man who should have been the honoured and rewarded head of that department has been lost to India to Liverpool's gain. To this day,

however, the best advice that can be given to the would-be recruit for the I.M.S. is as follows: Qualify at as early an age as possible. Do not waste time by taking up a resident medical appointment in your hospital, or in acquiring such useless lumber as an honour, degree, or a qualification in public health, but go up for the first examination that occurs.

As the keenness of the competition has a good deal diminished you will probably get in somehow; and your position on the list will have so little influence on your future career that six months seniority on the list will avail you far more than the kudos of being highly placed in the competition. The truth of this will be especially apparent towards the end of your period of service. Only the other day thirteen excellent officers were "passed over" for promotion simply because they were too old. There was no other reason; for the thirteen included men holding most distinguished records, and who, moreover, were known to be *personæ gratæ* with the authorities, who really had no choice in the matter.

Once in the service stick to routine work, preferably on the military side, as the civil branch no longer presents any particular pecuniary advantages, and you will have light, pleasant work, and serve in the pleasantest stations.

Above all, avoid all suspicion of originality or special ability in any particular direction, as it may lead to your being placed on "special duty," and when you return to the ordinary line of work you will find yourself penalised, as if employment of the sort were an indictable offence.

No one who knows the service will deny the soundness of the above advice, and it further cannot be denied that the fact of the expediency of such counsel reveals a state of things that urgently calls for reform.

For the routine work of the service, good, average men whose professional experience outside the lecture-room is strictly limited to India will always be available in sufficient numbers; but the Indian service includes so many appointments for which such humdrum credentials are entirely inadequate that every effort should be made to attract men of matured study and exceptional qualifications.

With this object the following reforms are respectfully suggested to the "powers that be":—

(1) The present age limits are absurd under modern conditions of medical education. Practically speaking, it is impossible for the ordinary student to qualify under two or three and twenty, and a man who completes his education by taking a resident medical officership and an honours degree cannot possibly enter till he is twenty-five or twenty-six, under which circumstances it is quite impossible for him to reach the highest ranks of the service.

The age limit should be absolutely done away with, and in its place a term of service substituted, say thirty-five years in the case of promotion to colonel, and thirty-seven in the case of surgeons-general.

To judge mankind by its years is a rule-of-thumb absurdity.

There are plenty of veterans of sixty who can hold their own even in practical field sports; and if men far in advance of this limit be physically and mentally fit to act as Cabinet Ministers they may surely be trusted to cope with the far lighter strain of the efficient conduct of the duties of director-general of a medical service. A man prematurely senile would presumably not be selected for promotion to so important a post; and if physically unfit, the ordinary mechanism of invaliding, which is applied to officers of all grades, may be trusted to deal with the difficulty.

(2) Every effort should be made to attract men of the highest qualifications.

It will not be enough to allow time spent as resident medical officer of a teaching hospital to count for service and pension. In addition, a monetary bonus should be given to successful candidates who have sacrificed immediate pecuniary returns to the desire for professional efficiency. The same arguments apply to the holders of honours degrees; that is to say, those that require more prolonged study than is exacted for bare qualification; the F.R.C.S. and the holder of a qualification in public health for example. To those who have gained such degrees a small extra allowance should be made.

Engineering firms find that they cannot obtain a fitter for the same wages as a rivetter, and to offer the same rate of pay that is given to bare qualification to the finest flower of the medical schools is to put into practice the ideals of the worst school of trades unionists who would reduce all workmen, bad, good, and indifferent, to the same dead level of remuneration.

In the sister service of the R.A.M.C. the expediency and justice of rewarding men for the labour involved in acquiring additional professional knowledge has been recognised by the grant of what is known as specialist pay. We consider, however, that while the principle of rewarding exceptional zeal and ability is entirely sound, this particular application is a mistake.

It is an abuse of the ordinary application of the word to dub as a specialist a young fellow who has merely passed a few months in the clinic of some special hospital; for men cannot be converted into specialists in the same way as the pork butcher turns out an Oxford or a Bologna sausage by stuffing a skin with varying kinds of meat.

True specialism can only be attained by those who have laboured to give themselves an exceptional general training, and have then devoted special study and observation to a particular class of cases; and the best evidence of fitness to be-

come a specialist is the possession of an honours degree.

At any rate, the plan is entirely inapplicable to a service in which a large percentage of officers have, for example, far better claims to call themselves eye specialists than the majority of London ophthalmic surgeons, numbering their successful operations by hundreds when the latter can boast only of tens. Just fancy the position of the young officer who presented himself before the university professor in charge of the Eden Hospital, Calcutta, as an obstetric specialist.

The system would be killed by ridicule; but no such objection could be raised to a special allowance to the holders of honours degrees, as all are well aware of the time and labour involved in their acquirement, and there can be no doubt that it would enormously stimulate post-graduate study within the ranks of the service.

THE HYGIENE OF TRAVEL IN TROPICAL AFRICA.

Professor Koch's valuable communication, a full translation of which appears in our columns, is naturally mainly occupied with etiological questions, but contains one very obvious prophylactic recommendation with respect to tick fever. This is to the effect that officers travelling should seek out fresh ground at halting places on which to pitch their tents. The proposal is a very proper and natural one, though it indicates a certain amount of unfamiliarity with the difficulties of tropical travel; for there are undoubtedly an enormous number of situations where, owing to the closeness of the jungle or the difficulty of obtaining supplies, it would be absolutely impossible to carry it into effect.

When a possession has passed beyond the stage of exploration, and has entered that of occupation and administration, officers must needs be continually passing to and fro, and it is clear that any such procedure is absolutely out of the question; and that to avoid interference with private rights, special camping grounds must necessarily be adopted even in fairly open country. Under such circumstances, Koch's recommendation becomes a mere counsel of perfection. What should be done is that at all habitual halting places, a sufficient space for the tents of one or two European officers should be fenced in, and if possible macadamised. Moreover, as quite apart from humanitarian considerations, it is most inconvenient and fatal to service efficiency that native subordinates and followers should become infected; a considerably larger space should be similarly hardened for their accommodation when bivouacking for the night.

The ticks harbour in dust, and are not so constituted as to be able to burrow into a hard surface, so that by insisting on such a ready prepared surface being swept, a very fairly efficient degree of protection would be afforded.

What, however, would Koch have said had he been dealing with the ordinary travelling customs in vogue in most parts of British Tropical Africa where our officers are unable to carry tents at all, owing to the insufficiency of the amount of transport allowed to them; and where our Colonial Governments actually countenance the unfortunate natives being turned out of their huts to afford their undesired visitors the necessary shelter for the night? Talk of Chinese slavery! here, indeed, is a splendid opportunity for an election cry utterly wasted.

The procedure is, of course, justified on grounds of economy, but is surely indefensible and impolitic from an administrative point of view; and the risks to which it exposes our officers are so great and obvious from our present standpoint of knowledge that it is marvellous that such a system should continue to be tolerated for a single day. To be bitten by infected ticks is, of course, only one of the dangers to which those who are forced to adopt such a repulsive shelter are exposed, as native huts necessarily swarm with malarial mosquitoes, and half a dozen other sorts of parasites of a more or less objectionable character. An order should be promptly issued that officers should under no circumstances sleep in native huts when marching, and proper tents and transport should be provided for them so as to obviate all necessity of resort to so terribly risky a procedure.

THE DEATH OF DR. STEWART.

The murder, under circumstances of peculiar atrocity, of Dr. Stewart, of the Nigerian Medical Service, is an event that cannot fail to impress the stay-at-home Englishman of the smallness of his knowledge of the conditions of life in an African colony.

To a scientific man, the contingency of being eaten afterwards, is one that adds little or nothing to the horrors of a violent death, beyond perhaps inspiring a grim hope that one may "disagree" with the digestive economy of one's murderers; but that an officer should be actually killed and eaten, not only well within the boundaries of a British colony, but no more than thirty or forty miles from its capital, gives rise to reflections that should give pause to those authorities at home who, though absolutely without local knowledge, have yet the last word as to the administration of these distant colonies. It is true that Nigeria has only come under British rule quite recently, but as a matter of fact, this debased appetite is a common characteristic of most of the tribes of Western and Central Africa; and though fear of consequences would, in the case of a

white man, render such an event extremely unlikely in the neighbourhood of Cape Coast Castle or Sierra Leone, few who know the country would care to deny that cannibalistic tastes are still prevalent, or that, amongst themselves, when safe from the eye of the ruling race, such occurrences are either impossible or even uncommon.

Evidences of cannibalism have been found even in Europe, though it is doubtful if these ancient cannibals were really Caucasians, and with this doubtful exception the Caucasian and Mongolian races have always regarded cannibalism with the horror that should be natural to any race that aspires to survive in the struggle of fitness. At any rate, if ever given to such practices, the white and yellow races abandoned them in the very earliest stages of the evolution of their civilisation, whereas the negro retains them long after emerging from the stone age, and even when he has made considerable advances in agriculture and in the arts of weaving and working in metals.

So inbred, indeed is this savagery, that even after generations of nominal Christianity in the West Indies, the rising in Jamaica, which wrecked the reputation of the much maligned Governor Eyre, was marked by such incidents as the scooping out of the brains of their European victims and the conversion of skulls into drinking cups. The irony of the situation, however, lies in the fact that under our system of administration it is quite possible that the very men who "chopped" poor Dr. Stewart may give trouble to his immediate successors, in the less congenial but more humorous guise of an obstructive village sanitary committee, or some such exotic organisation, based on the latest European models. Surely such an incident shows, *inter alia*, that at any rate in a matter as foreign to his philosophy as sanitation, it is essential that the negro should be ruled benevolently but despotically by the European.

BISKRA AS A HEALTH RESORT.

Biskra, the desert city, is an agglomeration of oases to the south of the Aurès Mountains which has become a very popular resort during the last few years. It is only 360 feet above sea-level and the climate is delightful for six months in the year. The temperature in the shade averages 60° F. during the winter season (November to May), and rain is practically unknown, the total annual fall not exceeding an inch and a half.

Within the sphere of influence of the carefully husbanded water supply the soil is remarkably fertile and vegetation is exuberant. The oasis of Biskra alone contains a hundred thousand date palms, besides other fruit-bearing trees, and this luxuriance of growth is in startling contrast with the surrounding aridity. There are plenty of objects of interest in Biskra and its immediate neighbourhood. The town, with its 8,000 inhabitants, is a typical example of "life in an oasis."

Abstract.

Flies and Cholera (Mouches et Choléra). By Dr. A. Chantèmesse and Dr. F. Borel. 1 vol. in 16. Price 1s. 6d. J. B. Baillière et Fils, Paris, 1906.

Cholera which started from India in 1900, had arrived gradually in the vicinity of Berlin in October, 1905. Has it reached the final limit of its onward march? It would be rash to state so. During the four preceding years cholera has apparently disappeared at the onset of the cold season, but has always resumed its progress in the early days of the following summer. We must therefore be prepared for a fresh extension of this epidemic which hitherto has been uncontrolled, in the first fine days of 1906.

Truly we may face this alternative without much fear, the progress of hygiene having provided us with arms of ever increasing efficiency for combating this scourge. Nevertheless, we have not as yet reached the time when it can no longer be feared. As yet we can only restrict the number of cases; it is difficult, on the other hand, to entirely prevent a manifestation of contagion, and the brutal fact of a contamination may at any time occur.

Drs. Chantemesse and Borel have therefore deemed it of interest to draw up in this small volume a schedule of the latest ideas on cholera collected by science since the last epidemic. Amongst these, there are at least two which appear to us to be specially worthy of notice, as a knowledge of them is of a nature to invite some important modifications in the prophylaxis of cholera. These are *latent microbism* and the *dissemination of the diseases of microbic origin by the intermediate agency of insects.*

A historical review of the several incursions of Indian cholera into Europe between 1817 and 1892 leads the author to the following conclusions. India is the original home of cholera, from which it spreads and reaches Europe by three different routes. The first is through Afghanistan and Persia; the second is by way of the Persian Gulf, Chat-el-Arab, and Persia; the third is that by Mecca and Egypt to the Mediterranean Sea. The progress of the various epidemics has been notably influenced by the amplification of the means of transport and by their ever-increasing ratio of speed. Thus in 1823 cholera did not go beyond the South of Russia. In 1830 and 1848 it took two years to invade the whole of Europe; whilst in 1892 this continent was completely affected in a few months.

Towards the end of 1899 and early in 1900 cholera in India again broke out with great severity both at Bombay and Calcutta; it then proceeded to the south of the peninsula, and thence gradually extended eastward to China and westward to Europe.

On the eastern route it attacked the Dutch Indies in June, 1901, and then in succession appeared in Singapore, Burmah, the Philippine Islands, China, Formosa, Japan, and Cochin China, and with deadly force afterwards in Manchuria and Corea, finally only ceasing its advance to the north on arrival at the end of the inhabited world.

To the west of India three routes lay open, all of

them equally familiar with this scourge. The land route through Afghanistan, the sea route *via* the Persian Gulf, and that through the Red Sea. Which of these three roads would it follow? Briefly stated, cholera, leaving India in December, 1901, reached Hedjaz in March, 1902, contaminated Egypt in July of the same year, and following the Mediterranean coast appeared in Damascus in January, 1903. After reaching Bagdad early in 1904 it passed on and ravaged Persia, and by July had attacked Bakoum on the borders of the Caspian Sea; from here it invaded on one side the Caucasus and on the other the Volga, which it ascended as far as Saratow, from whence it spread through Russia, finally appearing in August, 1905, in Eastern Prussia and in Austria.

In order to arrest the onward march of cholera, and especially if logical barriers are to be opposed to it, this march must be considered under the three following different aspects: its transportation, propagation, and dissemination.

Transportation is its extension from a contaminated country to a distant healthy region; *propagation* is its extension from town to town, or village to village, in a recently infected territory; and lastly, *dissemination* consists of the various methods of which the epidemic avails itself to spread in the same town from house to house, or from one individual to another.

Cholera can be *transported* to a distance only by healthy individuals, in whose intestines specific cholera vibrios may be found, although they themselves show no clinical symptoms of the disease.

Cholera may be *propagated* by the agency of individuals in a state of latent microbism, but also by clothing, &c., infected with choleraic dejecta, within five days, and by individuals in whom cholera is incubating.

Cholera may be *disseminated* in five different ways:—

(1) and (2) By linen and personal effects, if recently soiled by cholera dejecta.

(3) By drinking water, if the contamination can reach the wells, cisterns, or ground water.

(4) The actual patients will infect their surroundings by their dejecta, which represent pure cultures of the dangerous microbe.

(5) Healthy individuals may become a source of contagion for others, as their fæces in many instances will contain the cholera vibrio, which, although not active in their case, may yet become pathogenic for others.

Modern science now entitles us to say:—

In times of cholera, the dejecta of many people are receptacles of cholera vibrios; everything contaminated by these dejecta becomes in its turn a source of danger, so long as desiccation, disinfection, or spontaneous alteration have not destroyed its activity. The multiplication of the cholera microbe takes place in the digestive canal to the exclusion of other parts of the body, but not necessarily manifesting its presence there by any pathological trouble.

The prophylaxis applicable to cholera is, therefore, at once both restricted and yet amplified; it is restricted, since we know that all that is required is to destroy only the fresh dejecta wherever they may be found; it is extended, since we now know that all dejecta must be attacked, not only in the case of patients, but also those of men apparently in good health.

Now how does the cholera vibrio usually pass from these dejecta into the digestive tracts of individuals living in an infected area? Is it by drinking water? Not necessarily. By inhaling dust? No. Judging by the analogous cases of plague and yellow fever (which are also lessened in number, but not in intensity, during winter), may we not conclude that a similar effect, whilst not affecting the cholera vibrio itself, may, nevertheless, act on the intermediate agent which carries the germ and permits it to penetrate—if not indeed directly, at least indirectly—into the human stomach? Without mentioning the numerous insects which—especially in hot countries—might act this part, can we not find one, in Europe as elsewhere, answering in all points to the description of the intermediary required? We allude to the ubiquitous fly.

Natural history shows that a fly can transport cholera germs in two ways, either as an inert carrier (owing to the vibrios adhering to its feet or any other part of its body, and then being deposited on food), or by means of its proboscis, which retains and preserves the germs and redistributes them successively over different media, which, if favourable for their development, ensures their multiplication, especially if the temperature is also sufficiently high for this purpose. Several series of experiments prove that flies can disseminate cholera, but that this contamination disappears in about twenty-four hours after contact with the source of choleraic infection. We do not assign to flies an exclusive *role* of disseminating agents of cholera, for other modes have also a certain value. For instance, recently soiled linen may be touched by the hand, which may then touch one's mouth or food, and cholera thus be contracted. Water may become infected by infiltration with fæcal matter, and thus become the cause of part of the epidemic. We only here insist on a new method of dissemination which, conjointly with others, permits us to explain more completely the progress of cholera.

The prophylaxis against cholera is divided into several headings: *International*, *National*, *Urban*, and *Individual*.

International prophylaxis against cholera will probably remain an open question for very many years to come.

National prophylaxis can only play a restricted part in the defence against cholera; it can forbid entry on its territory of patients or of freshly soiled linen, but it is practically powerless against individuals in a state of incubation or of latent microbism, and it must delegate the ulterior and rigorous duty of keeping them under observation to the respective municipalities. *It is, therefore, to urban and individual prophylaxis that we must look to for successful protection against cholera invasion.*

Urban prophylaxis. The cholera microbe resides in the fæces of the sick and in those of many healthy individuals; therefore the urban struggle against the epidemic must consist exclusively in successfully dealing with the excreta, but this task is not one that

can be undertaken on the spur of the moment. The pail system and privies must be things of the past, and no town can cease to fear infection until its system of sewers is in a perfect condition, from its water-closets to its final and distant discharge outlets. Urban prophylaxis against cholera may, therefore, be summed up in a few words: *an incessant, determined and methodical fight against fæcal matter, before, during and after the epidemic.*

Individual prophylaxis against cholera depends on two main principles: the prevention of the cholera microbe from entering one's body, and if in spite of all precautions the microbe has found its way into one's digestive tract to prevent it from manifesting its presence there. To accomplish the first aim, the individual should attend not only to his drinking water, but also to his food in general. Water and milk should be boiled, food should be well cooked and served hot, and kept from flies; no food should be eaten which is not cooked at home; flies must be kept down—say, by formol—especially if the water-closets are defective, or if stables and manure heaps are in the neighbourhood. If, in spite of all precautions, the microbe has somehow managed to enter one's body, this latter should be protected from all causes which might bring about any intestinal trouble, such as chills, over-eating, unripe fruit, &c.; in other words, one should keep one's intestinal balance.

As regards the patient, since his dejecta—vomit and excreta—contain the dangerous microbe, everything that has been contaminated by these, or in contact with his mouth or anus, must be at once disinfected. The vessels containing the dejecta must be protected from flies whilst being carried about, their contents must be disinfected—or, better still, burnt, when this is possible—and the recipients then sterilised. The bed and the patient must be placed under a mosquito net, and the vessels which contain his food, drink, or medicines should be enclosed in a wired safe, so as to prevent all access thereto of flies. No meal should be taken in the sick-room, and hands should always be disinfected after touching the patient. In a word, prophylaxis consists in destroying the microbe at the very moment of quitting the patient's body, and before it has had an opportunity of becoming disseminated.

As regards the future, the land route from the East to Europe—the one already preferred by cholera—is about to be largely developed, and the plans have already been drawn up. There will be no protecting deserts, no lengthy sea voyages, during which cholera can be stamped out on board ship. The rapid propagation along the railroads will suffice to bring cholera into Europe every time that it undergoes the slightest recrudescence in the Indian peninsula. Urban prophylaxis alone will be able then to contend against the ceaseless threatening danger; the problem resolves itself into this: *Will the networks of the sewers be everywhere ready before those of the railroads?*

J. E. Nicholson.

Translation.

PRELIMINARY STATEMENT ON THE RESULTS OF A VOYAGE OF INVESTIGATION TO EAST AFRICA.

By R. Koch.

(Translated from the German by P. Falcke.)

In December, 1904, I travelled to German East Africa by commission of the Imperial (German) Government, to institute enquiries as to combating the Coast fever of cattle in the colony, which was said to be widely disseminated. For this purpose it was first of all necessary to confirm the actual spread of this disease in a reliable manner. It is a well-known fact that cattle from healthy regions become affected when they are taken to the infected coast, whereas those animals that are bred there remain healthy. It was accordingly resolved to import cattle from the principal stations of the colony to Daressalem, and to put them out to graze on severely infected pasturages, in order to test their liability or immunity to the disease.

In consequence of the great distances from which the animals had to be driven, it was two to three months before all arrived at their destinations, and I employed the time in the study of relapsing fever. The disease is undoubtedly endemic, but such cases as had been met with had always been mistaken for malaria, and it is only a year ago that the disease has been correctly diagnosed, by microscopical examination of the blood. Once attention had been directed to the disease its frequency was recognised, and investigations as to the cause of its origin were begun, leading to the conjecture that a species of tick might be implicated. I procured a number of these ticks, and succeeded in demonstrating spirochætæ, which appeared to be identical with the spirochætæ of relapsing fever, in some of them. This discovery naturally suggested the necessity of following up the question on the spot, that is to say, on the caravan track. I therefore undertook an expedition in company with Staff-Surgeon Dr. Meixner by the caravan route to Morogoro, a ten days' march.

Soon after our arrival there, we received the announcement by telegraph that cases of a disease, suspected to be plague, had occurred in the Rubeho Mountains, south of Mpapua, and that the outbreak had been preceded by a remarkable mortality amongst rats. This alarming news caused us to travel thither to see if there was an outbreak of actual plague. Fortunately we were able to establish that there had not been a single undoubted case of plague, and that the mortality amongst the rats had nothing to do with plague, but was caused by the larvæ of a gad-fly.

I then visited the Uhehe country, where two years ago a few undoubted cases of plague had occurred, and where recently a suspicious mortality had been observed amongst the rats. In this place also the rat mortality was found to be referable to the same larvæ.

During the march into the interior of the Protectorate I passed through many tsetse-fly localities. This was particularly the case on the homeward march, when I made a detour into the Uluguru Mountains in

order to investigate a rather important centre of leprosy. It had not originally been my intention to undertake any work on "tsetse," but the opportunity was so favourable that I was involuntarily drawn into investigations on the tsetse-flies. This took up a considerable time, but led to interesting results.

On my return to the coast I found that a number of oxen had arrived, and that some of them had already fallen ill with Coast fever and Texas fever. This afforded me an excellent opportunity to continue the investigations I had formerly begun in Rhodesia on the history of development of the piroplasma. In Rhodesia, in consequence of the unfavourable climatic conditions, I had not been able to make much progress, and had only discovered the first indications of a further development of this interesting parasite in the tick. I had now at my service a wealth of material in a climate suitable for the development of the ticks and the parasites they harbour. Here again, was a proof of how greatly the success of such research depends on the correct choice of time and place. This time I succeeded without difficulty in tracing the history of development of the piroplasma to the forms assumed in the ova of the tick.

In addition, I continued my study of the tsetse-flies, and as Daressalem was not very favourable for this purpose, I removed my headquarters to the biological experimental station of Amani, where there is a well-arranged laboratory, and around which the Usambara Mountains furnish extensive tsetse centres for study.

As I gained further rather important results in the course of these observations, I considered it expedient to visit Uganda before my return to Europe to gain personal information on sleeping sickness, and to ascertain in what measure my observations on the glossina of tsetse disease coincided with those on *Glossina palpalis*, the carrier of sleeping sickness.

I give here briefly an outline of the most important observations and discoveries I made in these expeditions, and hope later on to publish a detailed communication on the subject.

Relapsing Fever.

The relapsing fever which is prevalent in German East Africa differs in but few particulars from the European form of this disease. The brevity of the individual attacks is particularly remarkable, as also is the small number of spirochætæ discoverable in the peripheral circulation. The African spirochætæ appear to me to be, on an average, longer than the European variety. I have never seen chromatin bodies in the spirilli, which would have presumed their relationship to some trypanosoma; neither did I observe any indications of either an undulating border or of longitudinal division. On the other hand, gaps were frequently seen, which gave one the idea that the parasite increased by transverse division[1] (fig. 1).

Monkeys could always be infected with certainty by means of subcutaneous injections of "relapsing blood." The disease thus artificially induced ran a severe course, sometimes even terminating fatally. The spirochætæ are more numerous in the blood than is the case in man.[2]

African relapsing fever is transmitted by the bite of a tick.[3] This tick, *Ornithodorus moubata* (Murray), lives in the floors of the huts of the natives. At night it comes out, sucks the blood of the inmates, and again conceals itself in the floor during the day. They are also regularly found in the floors of the so-called *bandas*, or shelters under which caravan travellers pass the night, but only in those parts not exposed to rain. The ticks are probably distributed over the entire Protectorate, and are also found in localities far removed from caravan traffic.

When a tick has sucked the blood of a man or monkey suffering from relapsing fever the spirochætæ do not multiply, but in the course of a few days disappear from the stomach of the tick. If, however, such ticks be examined more minutely it will be discovered that in a certain number of them spirochætæ can be demonstrated on the surface of the ovary. This examination is effected in the following manner: The ovary is squeezed out of the tick, teased out on a cover-glass, spreading it out as much as possible, allowed to dry, and then stained with a solution of azur-eosin. The spirochætæ are then mostly found in such numbers and arrangement that a considerable increase must undoubtedly have taken place. This demonstration is most successful in cases where the ova are in an early stage of development.

After the ticks have deposited their eggs the spirochætæ will also be found in their contents. There are, however, only a few groups of eggs, and in these again only a few eggs which are infected. At first only single specimens or groups consisting of a few, are found in the eggs, later on they are more numerous and often form conglomerations (fig. 2). It therefore appears as if they continue to multiply within the egg. I have not observed any alterations which would lead one to construct a hypothetical cycle of development.

The young ticks from infected localities are capable of infecting monkeys on which they have been applied.[4]

Of the ticks examined for spirochætæ, 5·15 per cent. were usually found to be infected, and in a few cases this number rose to 50 per cent.

Infected ticks were found in all locations on the caravan route from Daressalem to beyond Kilossa, in the direction of Mpapua, and on the track from Kilossa to Tringa. They were also found in the villages of the Rubeho Mountains, and in locations away from the caravan routes.

Neither of the three Europeans who were with the caravan suffered from relapsing fever, because they

[1] The plate has been prepared from drawings made by Dr. Kudicke, with Zeiss' drawing apparatus, from the original preparations, and with an enlargement of 2,500, and redrawn in our office, as the blocks illustrating the German original were hardly sharp enough for advantageous photographic reproduction.—Ed. *J. T. M.*

[2] As far back as the end of 1903 Dr. Kudicke succeeded in transmitting African relapsing fever to monkeys.

[3] During the expedition I was unable to obtain the current literature of the subject, so that it was only later that I heard that that cute investigator, the late Dr. Dutton, had simultaneously infected monkeys with relapsing fever by the agency of ticks. Compare *British Medical Journal*, February 4th and May 6th, 1905.

[4] Hitherto I have succeeded eleven times in this experiment.

never passed the night in native huts, nor did they sleep in the *bandas*. Of the five native servants who observed no such precautions, four were attacked with the disease. Of the sixty carriers, none had relapsing fever, although they slept in huts or under the shelters. This was probably because they had been infected on former expeditions, and so acquired immunity.

Certain observations demonstrate that fever has always been widely distributed and endemic in German East Africa. The natives, as a rule, contract the disease during youth, and consequently acquire more or less immunity, so that they either escape or get only single slight attacks. The European can best protect himself from infection by pitching his tent only on spots which have not been used by others for camping.

Amongst the cattle examined by me in Daressalem I incidentally found that two oxen were suffering from the cattle spirillosis discovered by Theiler. In these animals also, I succeeded in tracing the spirochætæ to within the ova of the ticks.

(To be continued.)

Correspondence.

WYTMAN'S GENERA INSECTORUM. 26th Fasciculus.—Culicidæ. By F. V. Theobald.

The above publication may be presumed to mark the termination of the tentative stage of Mr. Theobald's work on the classification of the Culicidæ, and the presentation of his results in a more or less definite and final form, so that it may be opportune to consider how far the proposed classification can be said to fulfil its purpose.

Putting aside the *Corethrinæ* in which the structure of the mouth presents such radical anatomical differences, that, apart from the accidental similarity of their wing venation, no one would have thought of grouping them in the same family with the Culicidæ, it must be premised that the family is characterised by such uniformity of structure that there is no real need for multiplying the number of its constituent genera, apart from considerations of convenience. The difference in the proportional length of the palpi in the two sexes furnished the earlier collectors with the four genera that were alone firmly established when the writer, in 1900, published his compilation of published descriptions of species, but such a number was even then obviously insufficient, as the genus *Anopheles* included thirty, and that of *Culex* no less than 159 names.

Added to this, the hygienic importance of the family led to such great activity in collecting that an enormous mass of material, including some hundreds of new species, flowed into the British Museum, and the most difficult problem presented to Mr. Theobald, to whom the work of classification and examination was entrusted, was to find some plan of reducing the family into genera of more manageable dimensions.

This he believes he has has accomplished by the adoption of *scale-structure* as a basis of generic distinction, but it must be confessed that the result is somewhat disappointing, as the genus *Culex* is already more crowded than ever, and now includes no less than 175 species, and is still growing ; or, in other words, more than 44 per cent. of the four hundred and odd species enumerated remain crowded together as one of 67 genera enumerated.

Of these 67 genera no less than 52 do not contain more than four species, and 32 of these include but a single species.

In the *Anophelinæ*, where, not scale-structure but scale-distribution has been mainly relied on, the result is fairly satisfactory, in other words, in four or five of the thirteen or fourteen new genera; but whereas in the *Culicinæ*, scale-distribution is painfully uniform, the number of genera including but a single species is so large that it is obvious that the characteristics relied on, viz., that of scale-structure, is in no sense of generic, but merely of specific, value ; and, even in the *Anophelinæ* the same result has followed wherever scale-structure alone has been adopted for the distinction of genera.

The net result is that the identification of species would be far easier by a merely artificial system of tabulation, until some characters of better generic value than scale-structure can be hit upon, and this we appear to be as far as ever from discovering.

The fact is that any system which relies on one class of character alone is sure to break down in practice, because classification on such a basis, necessarily results in a grouping as little natural as a frankly artificial tabulation, with none of the advantages of the latter in the matter of ready recognition of species.

Some of Mr. Theobald's genera will no doubt stand, especially his earlier ones; the genus *Stegomia* forming undoubtedly, a fairly defined and natural group of species ; and the same may be said of *Mansonia*, through the weakness of scale-structure as a generic criterion must be evident to any one who is at the pains to examine closely the wings of the various species,, for why some of these should not be placed in *Tæniorhynchus*, if judged by their wing-scales alone, is a matter that is difficult to understand.

Coming to *Tæniorhynchus*, it can easily be seen, that while the original definition of Arribalzaga brought together a distinctly natural group, the modified diagnosis of Theobald excludes many obvious congeners and includes a number of undesirable aliens.

Space forbids any further criticism of individual genera, but the above examples should suffice to indicate the grounds that have gradually led the writer to regretfully abandon the use of Mr. Theobald's classification. Nor is he alone, for recent criticism shows that these opinions are shared by those whose position as professed entomologists entitles them to be constituted as judges on such a question.

Six months ago Captain James and Captain Liston, I.M.S., produced their monograph of the Indian anophelinæ, rejecting Mr. Theobald's classification for much the same reasons as those advanced above, though that work and the critiques on it had not been seen by the writer at the time the earlier portion of this article was penned, the dates being about contemporaneous.

The process of genus making, however, goes on as merrily as ever, for the worst of work of this sort is that it is infectious, and a busy group, including Blanchard in France and Miss Ludlow in America, seem to be conspiring to make the recognition of a mosquito an impossible task, even for naturalists, let alone for medical men. It may be well, therefore, to quote textually the opinions on this subject of two of our best known British dipterologists as expressed in the critiques above alluded to on James and Liston's work.

Mr. Verrall, in the *Entomologist's Monthly Magazine* for May, 1905, p. 121, says: "The writers do not profess to be ultra-scientific entomologists, and thereby show their common-sense, and probably better true science than the genus and species makers who have preceded them. At any rate there remains the fact that their species will be easily and accurately recognised, while the works of Theobald will prove stumbling-blocks for generations. They have wisely ignored the insufficiently distinguished genera of Theobald, which have commonly been founded on minute and practically indistinguishable characters, and which are consequently valueless to the 'field' naturalist."

In another review of the same work, which appeared in the *British Medical Journal*, June 10th, 1905, Mr. E. E.

Austen, if less emphatic, is obviously of the same opinion, as he records his opinion that "For the reasons stated, therfore, we are disposed to agree with the authors in their conclusion that while differences of scale-structure are undoubtedly of great value in the distinction of *species*, such differences as are present, at any rate among Anopheles are not sufficiently important to be considered of generic value."

Once this is admitted, the whole basis of Mr. Theobald's classification falls to the ground, but meanwhile the game of genus making goes merrily on, and each new species that comes to light is made a pretext for the establishment of a new genus. For the genus makers this amusement is doubtless highly satisfactory as a labour-saving expedient; because it is far easier to describe your species and call it a genus than to go to the pains and labour involved in fitting it in to some existing group; but it is quite the reverse for those who are frequently called upon to identify mosquitoes.

At the time of the issue of the second edition of the writer's "Handbook of the Gnats or Mosquitoes" the process had not gone far; and while somewhat distrustful of several of the new genera, the results were in many cases satisfactory and useful, so that, having nothing better to propose, and recognising the urgency of the subdivision of the unwieldy recognised genera, it was felt desirable to fall into line with so authoritative a publication as a British Museum monograph.

The growing complexity of the classification, as further evolved in the third or supplementary volume of the monograph, however, made him feel that any further adoption of the classification of the monograph would be a distinct mistake in a work primarily intended for the use of medical men, so that, in issuing his "Revision of the Anophelinæ," while employing Mr. Theobald's new names, the writer declined to employ his genera as a key to the recognition of species, feeling that neither he nor his readers could be trusted to sort out mosquitoes by the plan proposed. The memory of prolonged helpful correspondence and pleasant days of work together made him loth to bring this disapproval more prominently to notice, but the rapidly increasing rain of new genera is bringing such utter confusion to the subject that he feels it incumbent as one who, if not a professional naturalist, was yet the first to take up the subject systematically, to add his voice to the protests of those far better qualified than he to judge on such points.

G. M. Giles.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the Journal of Tropical Medicine *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"The Australian Medical Gazette," December 20, 1905.

An Epidemic of Acute Dysentery Occurring at Rutherglen. J. R. Harrison.

In Rutherglen, a town on the Murray River, Victoria, Australia, an outbreak of dysentery began on January 22nd, and lasted until June 6th, 1905. During this period 53 cases of typical dysentery were seen and treated by Dr. Harris, who reports the epidemic.

Of the 53 cases 7 were observed in children from 6 months to 2 years old, with four deaths; 11 cases occurred in children from 2 to 8 years old, with no deaths: the remainder occurred at ages varying from 15 to 79 years, and of these three were females, aged respectively 20, 22, and 27 years, and one male, aged 79, died.

Dr. Harris found treatment by bismuth, opium and mist. creta, ipecacuanha and pulv. ipecac. Co. and calomel, useless in the severest cases. He gave up these drugs in favour of Epsom salts, which he prescribed as follows:—

℞ Mag. sulp.		grs. xxx.
Acid sulp. dil.	}	āā ɱx.
Tinct. belladonnæ		
Liq. opii sedat.		
Liq. strychniæ		ɱv.
Aq. piperitæ		ad. ʒi.

One ounce every three hours.

This mixture acted immediately, and the results obtained were "all that any one could desire."

The cause of the outbreak was attributed to the water supply, which is laid on unfiltered from the Murray River, but analysis has thrown no light on the water being the source of infection.

The bacteriological results of the stools and of the blood showed:—

(1) No Shiga bacillus in the stools.

(2) A para-typhoid bacillus was present in excess of the common fæcal colons.

(3) The patient's blood yielded a positive agglutination reaction to the above bacillus, suggesting a causal relation between the bacillus and the dysentery.

"L'Europe Coloniale," December, 1905.

Un Mission a Lang-Bian. Dr. Vassal.

The author gives a vivid picture of the difficulties with which a doctor has to cope when working among semi-civilised people. The Annamese hiding themselves, or only consenting to have their children vaccinated when bribed with beads and tobacco; and it was only by availing himself of ostensibly chance scratches when vaccinating that he could get sufficient specimens of blood to establish the malarial index of the population. Two types of parasites were found—malignant tertian and the benign tertian—and 64 per cent. of the natives were affected. Dr. Vassal appears surprised to find malaria at Celoa in Reunion at a height of about 3,800 feet, but as a matter of fact, such an elevation is quite insufficient to affect the question in ordinary tropical or sub-tropical climates.

Original Communications.

RHINO-PHARYNGITIS MUTILANS (DESTRUCTIVE ULCEROUS RHINO-PHARYNGITIS): A PROBLEM IN TROPICAL PATHOLOGY.

By James Farquharson Leys, M.D.

Surgeon, United States Navy.

It is the purpose of this paper to call the attention of the profession to a pathological condition which prevails in only a few limited areas in the world, so far as known. This condition may, perhaps, be a late stage of frambœsia or yaws, or a sequel of that disease; or it may be a peculiar manifestation or a sequel of some other known or unknown constitutional disease. On the other hand, it may be a localised special affection, independent of any other disease, a disease peculiar to itself and caused possibly by a fungoid or bacterial invasion.

To introduce this subject to the reader's attention I cannot perhaps do better than quote at length from my annual report, as senior medical officer in the Island of Guam, to the Surgeon General of the Navy, for the calendar year 1904. The quotation follows:—

"*Rhino-pharyngitis mutilans.* (*Destructive ulcerous rhino-pharyngitis*). We have a disease to deal with which no one of us or of our predecessors has understood. We have no name for it except the descriptive one which I here propose. Many cases of it in the remoter pueblos and in the country have not been seen. The disease, early in its progress, affects the quality of the voice and in an advanced stage renders the face repulsive, so that many of its victims avoid public notice. Between forty and fifty cases have been seen, treated, and studied as long as they could be kept under observation. Many others are known to exist that will not present themselves for treatment. It is estimated that there are from 100 to 150 cases in the island. Among those seen regularly one case aged 3 and one aged 4 died, and another aged 9 was carefully observed and treated for several months, and was improving steadily, when she left Aqaña for Merizo. These three have been the youngest cases seen. The rest are of all ages up to eighty years.

"It is not unusual for a casual visitor here, even a medical one, to remark: "You have leprosy here, don't you? I met a leper as I was coming up the road." We can assure such an one that we have segregated all the known cases of leprosy in the island, and believe we have them all. He has met one of our noseless victims of rhino-pharyngitis.

Clinical Signs and Symptoms.

"The usual history of a case of this disease is as follows:—The patient, if seen early, as few are, complains of sore throat. On examination an ulcer is seen on the back of the pharynx, on a posterior faucial pillar, or on the free edge of the palate. It is superficial, movable, covered with a thin, dirty, brownish-grey pellicle of slough. This appears to be the initial lesion. The pellicle breaks down and leaves an ulcer which steadily increases, advancing up the throat into the posterior nares. The disease begins in the soft parts, but after reaching the soft palate and eating its way through its entire thickness, attacks the bone of the palate and nasal septum, finally destroying these entirely. The disease usually arrests itself at this stage, the ulcers healing, and leaves the victim with no septum, the nasal cartilage and skin fallen in, and the nose and mouth one large cavity. The disease rarely, if ever, advances downward from its starting point. The larynx is unaffected and phonation remains perfect, though articulation and the quality of the voice are sadly deranged, as in a bad case of cleft palate. In a few of the cases, fewer than 10 per cent. of them, the process is not arrested at this stage, and the ulceration destroys the cartilage and skin of the nose and advances upon the face. The upper lip always remains as a bridge across the large opening in the face; but above it, through the anterior nares, one looks into the mouth and down the throat. The tongue is unaffected.

Geographical Distribution and Etiology.

"The disease certainly appears to be of an infectious nature. The process is somewhat amenable to local surgical and antiseptic treatment, with tonics and iodides. But the infection is very difficult to eradicate, and though the process be apparently arrested for a time it tends to recur till it runs its course. Throughout the active stage of the disease, which sometimes lasts months or years, the patients, if so in the first place, remain muscular, well fleshed, and well blooded; their condition being thus in marked contrast to the anæmia and debility which accompany tuberculosis and secondary syphilis. It thus seems to be local, not constitutional, and this suggests that its cause may be of a fungoid nature.

"This disease appears to be known only in some of these islands of Polynesia. It is reported to be common in the Carolines. The local practicante here, an educated Filipino, practised five years in the Carolines before coming to this island. He holds a Hutchinsonian theory of his own that the etiology of the disease may be connected with the eating of rotten sun-dried fish, of which the Caroline Islanders are fond. The Chamorros of Guam have the same weakness. Dr. Daniels, of Fiji, quoted by Manson,[1] definitely excludes syphilis from its etiology, and thinks it may be a sequel of yaws. Dr. Alvarez,[2] of Honolulu, has expressed the opinion that it is syphilitic and has no connection with leprosy. In an allusion made to the disease in a report to the Governor of Guam in March, 1902, Surgeon Arnold, of the Navy, says he is not at all inclined from what he has seen of the disease to ascribe it to syphilis.

"The disease has been assumed by medical newcomers and casuals here to be a form (1) of leprosy, (2) of hereditary syphilis, (3) of tertiary syphilis, or (4) of tuberculosis, or (5) a sequel of yaws. There are good reasons for believing that it is none of these, but a peculiar, independent disease. I shall attempt to summarise these reasons.

---

[1] "Tropical Diseases," London, 1903.

[2] Personal letter to Surgeon W. F. Arnold, United States Navy.

(1) "*Argument against Leprosy.*—Only visitors not familiar with leprosy itself have ever thought that it was leprosy. Lepers are not known to suffer from this peculiar form of destructive ulceration and from its effects throughout life, and from no other sign or symptom of leprosy. Leprosy is sufficiently common all over the tropical world where this disease is not encountered.

(2) "*Argument against Hereditary Syphilis.* — It appears in healthy and well-developed persons of all ages, with no signs of hereditary syphilis in their own persons or in their brothers and sisters, and with no signs of syphilis in their parents.

(3) "*Argument against Tertiary (Acquired) Syphilis.* —Acquired syphilis is a common disease in most races over nearly the whole world. It is an extremely rare disease here, and neither primary or secondary syphilis has been seen in a native during the past year, among thousands of persons treated for other diseases, including several prostitutes. This disease is common here, and rare or unknown where syphilis is common. Dr. Daniels, who was in Fiji for years, states that there was no syphilis in Fiji at a time when the lesions observed in this disease were common. The appearance of the primary lesion of this disease in otherwise healthy children of healthy parents, at 3, 4, and 9 years of age, excludes acquired syphilis.

(4) "*Argument against Tuberculosis.*—The victims of this disease have no signs of tuberculosis in other organs or parts. The disease does not extend downward and become laryngeal. Instances are observed of several members of the same family all afflicted with only the peculiar lesions of this disease. Tuberculosis is common here as everywhere, and presents the same lesions here as elsewhere in the world. This disease is confined to a very small part of the world, so far as known.

(5) "*Argument against its being a Sequel of Yaws.*—Yaws is a very common disease in the tropical world. It is common here. About thirty cases have been seen during 1904, seventeen of them in school children (as noted above in this report). While a few of the cases of rhino-pharyngitis give a history of yaws, fewer still show any yaws marks or scars, and the large majority deny a yaws history. None of the three cases of children of 3, 4, and 9 years showed any evidence of having had yaws, and I think none of them had had it. The girl of 9 was a particularly handsome child, with a beautiful unmarked skin. Yaws is a very common disease among the negroes in the West Indies, but no sequel of yaws which resembles this disease is reported there. I have heard that yaws is common and this disease unknown in the Philippines. While it may or may not be true that in every place in Polynesia where this disease exists yaws also exists, yet there are many places where yaws exists and this disease does not. We are ignorant of the etiology of yaws, as we are of the etiology of this disease, and we have no reason, that I can see, to assume that they have the same etiology. I can see no evidence to warrant the assumption that this disease is a sequel of yaws.

"The study of this disease offers a fine field for the labours of any school of tropical medicine which might be disposed to send an investigator with a good equipment to this island."

This long quotation has been made as the best means of bringing this subject to the attention of readers to whom the condition may be as new and strange as it was to me when the above was written. My annual report on Guam, from which the quotation is taken, and of which it forms but a small part, was written under pressure for speed within the ten days following an unexpected detachment from that station by telegram. The part referring to this disease, which I have quoted here, was a hurried attempt to portray this condition, which was to me and my colleagues in Guam a pathological novelty, to the clinical and statistical aspects of which I had intended to devote special attention during the following year had I remained on duty there. During my Guam service no literature on this subject was available for reference except the very brief allusion to it in the article on yaws in Manson's *Tropical Diseases*. Some comment on it, with explanation and modification of some of the statements contained in it, is now in order.

The reference made by Manson to the opinion of Dr. Daniels is not by direct quotation. Manson's statement[1] is: "Daniels says that in Fiji, where syphilis is unknown among the natives, these destructive ulcerations of palate and nose, together with a skin affection like lupus vulgaris—all of which he says are amenable to potassium iodide—are not uncommon; he is inclined, therefore, to regard them as true sequelæ of yaws." I have since had access to some of Dr. Daniel's reports on this subject and will give his views in his own words. First, from an essay on this subject written jointly by J. S. Wallbridge and C. W. Daniels,[2] I take the following statements referring to Fiji: "There are a series of pseudo-syphilitic phenomena met with in the natives, *thought by some to have a connection with yaws*. Syphilis is unknown among the natives. First among these there is a destructive ulceration of the soft palate and fauces and sometimes of the nose. . . . I have twice seen this ulceration under 10 and it is common about twenty. In rarer cases it occurs late in life, and in one woman about 60, on whom I made a *post mortem*, the larynx was involved; there were no tubercles in any of the organs and neither gummata nor other signs of syphilis were present." "That syphilis is unknown amongst the Fijian natives is the experience of every medical man in that group."

Daniels,[3] writing later of yaws as he saw it in Georgetown, British Guiana, makes the following statements: "My experience of yaws has been gained mainly in Fiji. There it is called by the natives 'Coko,' and there can be no doubt that it is identical with the yaws I have seen in British Guiana." "Various ulcerations of the pharynx are met with later in life, and are *by some thought to be the sequelæ of yaws.*" "The chronic pharyngeal ulceration *attributed to yaws* appears much later than the eruption, and *I think is doubtfully caused by that disease.*" The clauses which I have italicised in these quotations give quite a different impression as to Dr. Daniels' views

[1] *Op. cit.*

[2] "Selected Essays and Monographs," New Sydenham Society, London, 1897.

[3] *Brit. Jour. Dermat.*, London, 1896. viii., 426.

from that which I had derived (rightly or wrongly) from the reference to them in Manson's book, quoted just before. Dr. Daniels evidently considered that there was little ground for the assumption that this pharyngeo-palato-nasal condition is a sequel of yaws, or at least he appears to have considered it only an assumption unsustained by any proof. His view would appear to be very much the same as my own.

My reference to Dr. Alvarez, of Honolulu, as holding a belief that these lesions are syphilitic is misleading, and I must correct the wrong impression it might give. I do not know that Dr. Alvarez has ever seen this condition in Fiji, Guam, or any other place in Polynesia. Surgeon W. F. Arnold, one of my predecessors in Guam, impressed by the prevalence of these lesions there, wrote to Dr. Alvarez, at Honolulu, asking him if these lesions were seen there, and if he believed them to have any connection with leprosy. Dr. Alvarez's letter in reply was left on the medical file at Guam, where I read it. His reply to this point was, in substance, that a few people were to be seen among the Hawaiians whose palates and noses had been destroyed by disease, that the lesions were not leprous, and that he regarded such cases as were seen in Hawaii as probably tertiary syphilitics.

In the "Argument against Tuberculosis" I have stated that the disease "does not extend downward and become laryngeal." This is a rule which, like most other medical rules, must admit an occasional exception, as in the one case referred to in the essay of Drs. Wallbridge and Daniels, and quoted above.

In the argument against its being a sequel of yaws, I said: "Yaws is a very common disease among the negroes in the West Indies, but no sequel of yaws which resembles this disease is reported there." This statement was made in ignorance of the literature. As already stated, at the time when this report of mine was written I had not seen any reference to such a pathological condition as the one under discussion except the allusions to it in Manson's chapter on yaws, which I have already mentioned and partly quoted here. I had travelled extensively in the West Indies, had a personal acquaintance with several medical men in the islands, had often discussed professional subjects with them, and I had never heard such a condition mentioned. I had supposed that Dr. Daniels was the first to call attention to it.

Similar lesions, however, similarly assumed to have a connection with yaws, were briefly mentioned by Dr. James Maxwell,[1] in 1839, as having been observed by him in Jamaica.

Certain indolent nose and throat lesions were described by Professor Breda[2] as having been observed by him in Italy in the persons of three Italians who had emigrated to and returned from Brazil, which lesions Professor Breda assumed to be due to a frambœsial infection. From his description of these lesions, however, and from the coloured plates accompanying his article, it would appear that the conditions seen and reported by him were entirely different from that described by Dr. Rat in Dominica, by Dr. Daniels in Fiji, and by myself in Guam. In the personal and clinical histories of these three cases, moreover, Professor Breda gives no facts sufficient to connect them with yaws, a disease of which he had only heard and never, himself, had any professional experience.

Lately I have access to Dr. J. Numa Rat's admirable treatise on Yaws,[1] published in 1891, in which the author describes these naso-pharyngeal lesions, which he regards as belonging to a tertiary stage of yaws.

After the report of the Surgeon-General of the Navy, containing a part of my Guam report, had gone to press, I requested the proof-reader to strike out the statement I had made that no such condition as this had been reported in the West Indies. In Dr. Rat's treatise (1891) the author says:—

"Destructive ulceration of the nares, pharynx and soft palate is one of the later manifestations of yaws. The affection generally begins as a tubercle at one of the parts above mentioned. When it originates in the nose, the early symptoms are those of ozæna; and the ulceration spreads from this organ to the palate and pharynx. It often, however, avoids the nares and commences in the soft palate. The ulceration of the tubercle extends thence, destroying the uvula and velum palati, and the septum nasi, and deeply scoring the pharynx.

"This ulceration may occur twenty years after the last traces of the secondary symptoms, even though the disease had lasted a short time only, and had been apparently effectually expelled from the system, and though the patient may be robust and in apparently good health. It generally begins about the age of puberty in those cases in which the earlier symptoms occurred during childhood; but it may also commence in childhood, and soon after the secondary period.

* * * *

"After a week the patient either develops the symtoms of ozæna, or complains of sore throat. On examination, the tubercle may be readily detected in the anterior nares, or a mirror will reveal the tubercle behind the uvula. After about a month ulceration begins; and, in a month or six weeks more, the uvula, velum palati and septum nasi have disappeared, and the pharynx is deeply grooved and covered with a greenish-white tenacious secretion. . . .

"The ulceration usually ceases about the palate after destroying the uvula and velum palati; but it usually lingers chronically about the posterior nares and pharynx.

"Adhesions may occur between the velum palati and the pharynx, and the posterior nares may be blocked by an excessive growth of granulation tissue, which may also project downwards as far as the œsophagus, leaving a very narrow passage by which respiration and deglutition are performed with great difficulty.

"The percentage of those attacked with the milder form of this ulceration is considerable in some localities in which yaws is endemic. In a district with a population of about 2,000, sixty persons thus afflicted have come under my notice, and possibly many more in the same place were similarly afflicted. It appears to

[1] "Observations on Yaws." Prize Essay. Edinburgh, 1839.

[2] "On Brazilian Frambœsia or 'Boubas.'" *Archiv f. Dermat. u. Syph.*, 1895.

[1] "Yaws; Its Nature and Treatment." London: Waterlow and Sons, 1891.

be specially prevalent in certain parts and rare in others.

"The above figures refer to a certain quarter of the windward district of Dominica, in which it is exceedingly common, and to which it seems to be entirely limited in that island. It is, on the other hand, very rare in South America and the West Coast of Africa, where comparatively few cases came under my observation."

I have not observed any lesion in the nose or throat, either in an early or late stage of this disease, which could be described as a tubercle, nor have I seen the excessive growth of granulation tissue interiorly which is described by Dr. Rat.

In far-advanced and aggravated cases I have seen such granulation tissue externally on the face, on the conjunctivæ, in the eyelids, and in the ulcerating alæ of the nose. It is shown in the eyelids in the accompanying photograph of one of the Guam cases. The only inflammatory process I have seen inside is the

serpiginous ulceration of both soft parts and bone, and the narrowing of the pharynx in some of my cases was brought about entirely by the adhesions and scar-contractions described by both Dr. Rat and myself. With these exceptions noted, his description of the local pathological process and mine are quite similar in all essentials, and I cannot doubt that the condition he describes as so prevalent within a limited area in the island of Dominica is the same that I have seen in Guam.

Manson[1] says: "Corney, in his annual statistical return of the Colonial Hospital, Fiji, 1896, classifies eleven cases under the heading 'Lupoid Ulceration of Posterior Nares and adjoining Pharyngeal Parts (tertiary framboesia)'" Surgeon J. C. Pryor, United States Navy, informs me that when he visited Fiji in December, 1899, Dr. Lynch showed him several such cases as "tertiary yaws." From these statements I infer that the assumed connection between this serpiginous ulceration of the naso-pharynx and yaws has come to be quite generally accepted by medical men in Fiji.

In December, 1905, I had the pleasure of becoming personally acquainted with Dr. Rat, in the course of a visit to the island of Nevis, where, as an officer of the Colonial Medical Service, he is at present stationed. I submitted my own observations and views on this subject, as contained in my Guam report, to him, and we discussed the subject at some length. Dr. Rat is one of two medical officers in Nevis, and has his residence in the district known as Gingerland.

In Dr. Alfred Nicholls' "Report on Yaws in the West Indies,"[1] C. R. Edwards is quoted as having reported the existence of between 300 and 400 cases of yaws in Nevis in 1886; and it was stated for January, 1889, that "in that part of the island known as Gingerland there are probably several hundred cases." As Gingerland is one of several medical districts in the island, and as the total population of the island at that time was given as 13,087, it will be seen that when that statement was written sixteen years ago yaws was excessively prevalent in the Gingerland district, and it is evident, too, that the disease has been generally prevalent in the island for at least twenty years past. Dr. Rat states that it is still excessively prevalent in the island. Dr. Rat was in charge of the limited area in Dominica which has been already referred to, and in which he observed this destructive rhino-pharyngitis to be so common for a period of only eighteen months, and in that short time sixty cases of such lesions came under his observation. At the time I visited him he had been one year in the neighbouring island of Nevis, yaws being excessively prevalent there and having been so for many years. In that one year he had not seen a single case of these naso-pharyngeal lesions in the island of Nevis; and this notwithstanding that the population under his observation in Nevis is much larger than that of the limited district in Dominica in which the rhino-pharyngitis was so common; and that yaws is about as prevalent in the larger Nevis population as it is possible for it to be in any population, and it has been so prevalent, excessively prevalent, there for at least twenty years. Dr. Rat told me that he based his belief that the destructive rhino-pharyngitis of the Dominica district was connected with yaws, was a late or tertiary development, or a sequel of yaws, entirely upon the coincident prevalence of this rhino-pharyngitis in a place where yaws was an excessively prevalent disease. The assumption had, or has, no other basis, and, if I understand his present attitude on the question aright, he feels that such an assumption can be only a tentative one.

Rhino-Pharyngitis and Yaws not Coincident.

If, in the absence of any exact knowledge of its etiology, the prevalence of this peculiar destructive rhino-pharyngitis were coincident with the prevalence of yaws, the assumption of a connection between the two would have a fair basis of probability. But from the facts here set forth it does not appear that there is any such coincident prevalence. The very few spots

[1] *Op. cit.*

[1] "Report on Yaws," by H. A. Alford Nicholls. London, 1894.

in the world, only three or four in number, from which we have reports of the striking prevalence of this rhino-pharyngitis are all in the tropics, and all happen to be in regions where yaws is common. But in all of these regions tuberculosis is common; in all but one, Fiji, syphilis at least exists, and the prevalence of this disease is no more coincident with the prevalence of yaws elsewhere than it is coincident with the prevalence of tuberculosis and syphilis elsewhere.

It may help the European reader to realise the extensive and striking prevalence of this rhino-pharyngitis in the few limited regions from which it is reported if he will apply the figures representing its prevalence in Guam (1 to 1·5 per cent.) or in the Dominica district referred to by Dr. Rat (3 per cent.) in some populations with which he is familiar. Any single case presenting similar lesions in Europe would probably be put down to tuberculosis or tertiary syphilis. But only a very trifling percentage of the syphilitic or of the tuberculous present such destructive lesions of the palate and nose, and the percentage of the total population so affected is insignificant. Suppose, however, the general prevalence of tuberculosis and syphilis and the occasional occurrence of lupoid and tertiary syphilitic nose destruction to be just as they actually are in London and other large cities and towns throughout England. And suppose that in Liverpool alone 3 per cent. of the total population were afflicted with a destructive and mutilating serpiginous ulceration of the naso-pharynx, usually self-limited and having little or no effect upon the general health. In the population of Liverpool some 25,000 persons so afflicted would be at large. And if these lesions were attributed by anyone to tertiary syphilis, we would ask why syphilis should bring about such a state of things in Liverpool and not in any of the neighbouring towns where it is equally prevalent. The percentage of the Dominica district applied to the population of London would give us 180,000 persons with peculiarly mutilated throats and noses at large in the metropolis, a condition of things which would attract some attention, and lead to efforts to ascertain its cause.

At the time I write, January, 1906, after a year's reflection on this subject, I am not inclined to modify materially the opinions expressed a year ago in my Guam report. I think this condition presents a problem in tropical pathology which deserves investigation, that no evidence has yet been adduced to warrant our regarding it as a late manifestation of yaws or of any other constitutional disease, but that it is more probably a peculiar and independent local disease. I think that it may not improbably be caused, like blastomycetic dermatitis, or like madura foot, by the local invasion of some infecting organism, though I am far from wishing to advocate this or any other mere hypothesis as to its etiology.

H.R.H. the Prince of Wales opened a new medical school at Lucknow during his visit to that town.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

FEBRUARY 15, 1906.

THE PROBLEM OF MEDICAL AID IN SEMI-CIVILISED COUNTRIES.

POVERTY, nationally speaking, if not of the individually biting sort, is a common characteristic of incomplete civilisation, and it naturally follows that countries in this stage of development cannot afford to pay for the services of the fully-trained medical product of advanced civilisation in numbers at all adequate to meet the total demand of their population for medical services.

Half a loaf is, however, proverbially better than no bread, and to at least partially meet the necessities of the case there arises the need for the organisation of a lower and cheaper grade of professors of the healing art. It is only lately that the plan has been abolished in France, and traces of it still remain in our English medical titles, if not in actual practice; while in Russia it is a present fact, but for which the medical examination of that Empire would be even more incomplete than it is.

But if, throughout the enormous temperate regions occupied by the Anglo-Saxon race, there is fortunately no longer any need for an inexpensive makeshift of this sort, it is by no means the case in the even vaster portions of the British Empire, where the white man rules and directs, but cannot colonise in the true sense of the word. "Exeter Hall" may rave in its fanatical ignorance, but is powerless to check the instinct of exploration; and once the white man has gained a footing within savagedom he can no more help ruling than oil can avoid floating in water.

Amongst the first in the field, medical men are always to be found, and their services are always so thoroughly appreciated by the indigenous races that their work forms one of the surest and most effective agencies in reconciling the native to the yoke of civilisation.

The demand for skilled medical aid soon, however, becomes far beyond the scanty financial resources of races which are but taking their first lessons in the arts of modern civilisation, and it becomes an urgent necessity to supplement the supply by training locally an inferior grade of practitioner, which, if not educated up to the standard demanded in older and richer civilisations, is yet capable of doing excellent work under more skilled supervision, and of forming an invaluable agency for the promotion of health and civilisation.

In India this need has long been recognised and catered for by the formation of a distinct branch of the medical service, known as Hospital Assistants. The members of this service are usually drawn from families of good caste, and in small but increasing proportion are sons of soldiers in the native army, a status which counts for a good deal in India.

They go through a three years' course, conducted in their own language, by professors who have graduated in our Indian Universities, working under the superintendence of an European superintendent belonging to the Indian Medical Service, but who, unfortunately, has usually so many other duties that it is impossible for him to take any real personal share in the work of teaching.

The course is quite gratuitous, the students even receiving a subsistence allowance; and on its successful completion they are drafted into the civil or military branches of the medical organisation according to requirements.

The training is an extremely practical one, and if not exactly scientific practitioners, the men who have undergone it have learnt enough to deal with all ordinary emergencies in quite effective fashion, and, in point of fact, form the very backbone of the great and somewhat complicated mechanism for popularising modern science in India; for it is the Hospital Assistants in charge of the little "branch dispensaries" which are dotted everywhere over the country, who represents medical enlightenment for the great bulk of the people. He may know nothing of the communications of the cranial nerves, or of the significance of the tendon reflexes, but he has a good working knowledge of the whereabouts of the great arteries, and may be trusted to treat you for fever or dysentery intelligently and efficiently.

Many, of course, become a great deal more than this by qualifying themselves to read and understand English books, and by observing the practice of their European superintending officers, so that some of them are excellent operators and very sound practical physicians.

In the military branch they now very properly rank as native officers, and very often the grey-bearded old senior assistant is the father of the regiment, and one of the most respected members of the corps.

The success of the Hong Kong Medical School, which we comment on elsewhere, though, of course, it aims at a fuller training, is a good example of what can be done in this direction, and will, we hope, draw attention to the desirability of instituting a similar organisation for the purposes of our African colonies. British Tropical Africa rivals India in area, and now that we are beginning to effectively open up the resources of the back-country the need of a body of medical officials of the type indicated will become increasingly apparent.

Fortunately, our old-established settlements on the West Coast can supply us with an ample number of educated and intelligent Africans to form the *personnel* of such an establishment, so that all that is needed is the mechanism for their education.

For this no elaborate arrangements are necessary, as no costly laboratories and apparatus are either needful or desirable.

The first year should be devoted to teaching visceral and regional anatomy, rudimentary physiology, and enough of the elements of chemistry to make the instruction in dispensing intelligible; while the remaining two years should be given up to the practical work of the profession.

Nor would any large teaching staff be required, as a couple of whole-time professors—one a young officer fresh from home, and the other an experienced Colonial surgeon—would amply suffice, though doubtless, as the school progressed, it would be desirable to strengthen the staff by utilising some of the best of the trained men as demonstrators and assistants.

We are not so sanguine as to hope that such an idea is likely to be acted upon at present, but put it forth in the hope that it may be considered and elaborated in due time by those who are entrusted with the medical organisation of our African Colonies.

AN EXPERIMENTAL REPRODUCTION OF AMŒBIC DYSENTERY BY INTRAVENOUS INOCULATION OF PUS FROM A HEPATIC ABSCESS.

By Surgeon-Major A. GAUDUCHEAU.
Director of the Vaccine Laboratory of Tonkin.

IT is well-known that abscess of the liver is often a complication of dysentery in warm climates, and although our knowledge of the pathology of these infections is still very incomplete, it appears that these diseases are due to amœbæ. In a recent work L. Rogers was able to trace the parasite from the intestine to the liver. Nevertheless, the amœboid nature of hepatic abscess has not yet been entirely elucidated, as the experimental reproduction of this lesion has not been realised.

Dr. Gauducheau therefore tried an experiment on new lines.

He obtained some fresh hepatic pus from an European patient. The pus was not sterile, as is often the case, for he was able to isolate three forms of bacilli from it, (1) the pyocyanic one, (2) a bacillus 3 μ in length, which he would have identified as Shiga's had it not been for its marked motility, and (3) a liquefying bacillus. He made an emulsion of equal parts of pus and salt water, and injected 4 cc. of the mixture into a mesenteric vein of an adult native dog. After an incubation period of 4½ days the animal (which had shown no sign of intestinal trouble up till now) was seized with characteristic dysentery. During the three first days after the onset of the illness the fæces contained numerous amœbæ, 20 μ long, moving with rapidity; they then became more rare, and during the last few days that the animal lived could not be found at all; the motions remained numerous throughout, but towards the end consisted almost entirely of pure blood. The animal died on the eighth day.

The *post mortem* showed the whole of the mucous membrane of the large intestine scattered over with bright red spots, in confluent patches or isolated, surrounded by a small inflammatory zone, but without any ulceration whatever; the line of demarcation was very noticeable, the diffuse inflammation suddenly ceased at the cæcum. The rest of the intestines were quite normal, as were also the other viscera.

In a word, whilst trying to reproduce abscess of the liver by a portal injection, Dr. Gauducheau obtained amœboid dysentery. Although the only one up to date, this experiment demonstrates the convertibility of the infection of suppurating hepatitis and dysentery.

Hanoi, December 1st, 1905.

THE post of Residency Surgeon in Kashmir is almost the only appointment in the hills open to medical officers attached to the Indian Political department.

In place of the "malarial focus," where he usually has to put in his time, the holder finds himself in one of the most delightful of climates; and as a change to the usual hard work of practically administering all the medical institutions of a native state, his duties are purely advisatory and correspondingly light; though far from a sinecure, in view of the number of health-seekers who now annually invade Kashmir. Under these circumstances the post has been very properly regarded as an exceptional one, which should be reserved for men whose health had suffered from the arduousness of service in the ordinary political posts, as it affords an opportunity, advantageous alike to the individual and the state, for an officer to recover his health without the expense of taking or giving furlough.

Recognising these facts, it was officially laid down in the time of that admirable administrator, the late Surgeon-General Harvey, that the appointment should not be tenable for more than five years, and there can be no possible doubt as to the wisdom and fairness of the order, though the period might perhaps have been curtailed to two or three years with advantage to the Service.

We hear, however, that this wholesome rule is to be abrogated in favour of the present holder of the appointment, who is to be allowed to hold it indefinitely.

It may be admitted that the officer in question has an exceptionally brilliant record, but there are other ways of rewarding and of utilising his talents than that of consigning him permanently to this Indian Capua, and we trust that should this meet the eye of the Secretary of State for India he may enquire into the matter, and should there be any foundation for the rumour, place his veto on what might be described by ill-natured people as something very like an instance of "influence."

THE COLLEGE OF MEDICINE FOR CHINESE, HONG KONG.

WE are pleased to gather from the Calendar for 1906 that this College thrives. No fewer than thirty-five students are in attendance, and since 1892, when the first students took their diplomas, twenty-four men have attained that honour. The examinations to which the students are subjected are maintained at the standard of examinations for degrees and qualifications in Britain. The Chinese, as any one who has had to do with young Chinamen either at home or abroad knows, are excellent students, earnest, hard-working, easily taught and intelligent to a degree. The list of teachers shows that the various subjects are taught by men not only well qualified, but many of them experts in their subjects. Of the original teachers in the College in 1887, when the College was first founded, one is rejoiced to see that the Honourable Dr. Ho Kai, C.M.G., Dr. Gregory P. Jordan, and Dr. J. C. Thomson, still give their valuable services to, and preserve their interest in, the College. Dr. Thomson has, by his tact and organising ability, done more than any other member of the staff to maintain and forward the interests of the College. The medical men resident in Hong Kong, past and present, ably assisted by local scientific men and medical officers of the Army and Navy on the Chinese Station, have, for many years, without pay or reward, given their time, experience, and in many cases their money, to further the interests of the institution. The work these medical men are engaged in is imperial in the widest and best sense of the term; they are presenting modern medicine, and particularly British medicine, at the gates of China, and offering the best they have to give to the people of China. It is easy to wax eloquent over such a theme, but even the most facile pen or fluent speaker cannot do justice to the possibilities of the work the staff of this College are engaged in. Could, however, the possibilities be brought home to the people of the Empire the students of the College would be as many thousands as now they are tens. Much good work has been and is being done, but the lack of encouragement from those in power, or possessed of means, leaves the College de-

pendent upon the self-sacrificing efforts of a few busy doctors, who have to give the few hours they can snatch from their daily toil in a tropical climate to instruct the students without pay, reward, or recognition. Could the meaning and importance of this College be brought home to British folk we would have in Hong Kong a teaching University of the first rank; and instead of turning to Japan, where German is the scientific language of the class-room, the Chinese would turn to an institution where the foreign language they are best acquainted with—namely, English, is the medium of instruction. The prestige accruing to Britain and British medicine, were this fulfilled, must surely be apparent to all, however narrow their imperialism; and it only wants one Governor of the Colony of Hong Kong to take the matter in hand and appeal to the patriotism of the nation to develop a scheme of superlative importance to the welfare of China and to the pre-eminence of Britain in the China Seas.

Abstracts.

MOSQUITOES AND YELLOW FEVER (Moutiques et Fièvre jaune). By Dr. Chantèmesse and Dr. Borel. 1 Vol. in 16. Price 1s. 6d. Baillière et Fils, Paris.

The subject is introduced by the following quotation from Article 182 of Chapter V. of the "Sanitary Convention of Paris, 1903," on the subject of yellow fever:—

"The countries specially interested are recommended to modify their sanitary regulations in such a manner as to bring them into relation with the actual data of science on the method of transmission of yellow fever, and especially on the part played by mosquitoes as carriers of the germs of this disease."

The following points have been established:—

(1) That the virus of yellow fever circulates in the blood.

(2) That the mosquito *Stegomyia fasciata*, after being itself infected for *at least twelve days*, is capable of propagating the disease.

(3) That *Stegomyia fasciata* is the only mosquito capable of playing this part.

The whole world is therefore divisable into two vast regions; in the one *Stegomyia* can live, it is consequently liable to infection by yellow fever; in the other *Stegomyia* cannot exist, and it is therefore not liable to become infected.

The Stegomyia mosquito is widely distributed round the earth, but its habitat is strictly defined by the two parallels of 43° of latitude, both north and south; it has never been found outside these limits, and any country situated beyond these parallels ought to be free from yellow fever.

A temperature of about 82° F. is necessary to enable the Stegomyia to exist in a normal condition, and more especially to carry on its functions of reproduction, so that even under the most favourable conditions if a few specimens of this insect were brought to France or England by a ship, although they might live for some days, their reproduction could not take place.

A country liable to infection may become contaminated in one of two ways:—

(1) If a patient in the dangerous stage of yellow fever is admitted thereto, and if Stegomyia is found to exist there permanently.

(2) By the importation of Stegomyia mosquitoes previously infected, which after contaminating healthy human beings, then find the conditions necessary for their existence, and especially for their multiplication.

An interesting historical and critical study of the several local outbreaks of yellow fever in Europe is now given at some length, and from which the following conclusions are arrived at:—

Yellow fever has almost entirely disappeared from Europe since 1870; the improvements in shipbuilding since this date have rendered difficult the preservation, and especially the multiplication, of mosquitoes on board modern vessels; there is no insurmountable difficulty in eliminating from our ships the chance specimens of Stegomyia which might occasionally stray there (especially in the engine-rooms), and in thus suppressing the last chances of propagating yellow fever in our own country.

The prophylaxis of yellow fever may be summed up as follows:—

In countries where Stegomyia exists, the patient should be protected from mosquito bites, and the insects should be destroyed wherever possible, as also their breeding grounds.

In other countries, yellow fever may be considered as a non-contagious and non-transmissible disease, calling for no special measures. The bodies of persons dying of yellow fever in the Colonies may therefore be brought home.

J. E. NICHOLSON.

SOME OF THE REGULATIONS CONCERNING PLAGUE, CHOLERA, AND YELLOW FEVER DRAWN UP DURING THE SECOND INTERNATIONAL SANITARY CONVENTION OF AMERICAN STATES, OCTOBER, 1905.

(i.) IMMEDIATE notification of the disease, stating place, date, number of cases, and, in the case of yellow fever, whether the mosquito *Stegomyia fasciata* is in the locality; and in the case of plague, whether rats or mice are infected.

(ii.) Foreign countries to be notified through their Consuls, and weekly notifications to be issued until the outbreak ends.

(iii.) The exact limits of the area imputed to be infected to be declared.

(iv.) Neither plague, cholera, nor yellow fever can be transmitted by merchandise. It only becomes dangerous in case it is soiled by pestous or choleraic products, or, in the case of yellow fever, when the merchandise may harbour mosquitoes.

(v.) All rags and clothing from districts infected by

cholera or plague suspected of being soiled are to be disinfected or destroyed.

(vi.) Ships infected with plague are to be subjected to the following regulations :—

(1) Medical visit (inspection).

(2) The sick are to be immediately disembarked and isolated.

(3) Other persons should also be disembarked, if possible, and subjected to an observation which should not exceed five days, dating from the day of arrival.

(4) Soiled linen, personal effects in use, the belongings of crew and passengers which, in the opinion of sanitary authorities, are considered as infected, should be disinfected.

(5) The parts of the ship which have been inhabited by those stricken with plague and such others as, in the opinion of the sanitary authorities, are considered as infected, should be disinfected.

(6) The destruction of rats on shipboard should be effected before or after the discharge of cargo as rapidly as possible, and in all cases with a maximum delay of forty-eight hours, care being taken to avoid damage of merchandise, the vessel, and its machinery.

For ships in ballast this operation should be performed immediately before taking on cargo.

(7) On ships suspected of plague the crew and passengers may be subjected to observation, which should not exceed five days, dating from the arrival of the ship. During the same time the disembarkment of the crew may be forbidden except for reasons of duty.

The destruction of rats on shipboard is recommended. This destruction is to be effected before or after the discharge of cargo as quickly as possible, and in all cases with a maximum delay of forty-eight hours, taking care to avoid damage to merchandise, ships, and their machinery.

(vii.) If an area should no longer be considered as infected, official proof must be furnished :—

First : That there has been neither a death nor a new case of plague or cholera for five days after isolation, death, or cure of the last plague or cholera case. In the case of yellow fever the period shall be eighteen days, but each Government may reserve the right to extend this period.

Second : That all the measures of disinfection have been applied ; in the case of plague that the precautions against rats have been observed, and in the case of yellow fever that the measures against mosquitoes have been executed.

Notes and News.

Nursing in India.

The hospitals administered under the Dufferin Fund and the Victoria Memorial Scholarship Fund have increased their surgical and nursing staffs since 1898 by no fewer than ten lady doctors, seven assistant surgeons, and 337 hospital assistants and women. The number of women trained at the hospitals amounts to 447. The Victoria Fund, founded by Lady Curzon in 1901, has trained 160 native midwives, of whom many are doing excellent work.

The Philippine "Journal of Science."

The Government of the Philippines are publishing a "Journal of Science," commencing January 1st, 1906. The Journal is replacing the Bulletins of the Bureau of Government Laboratories, and will include the reports of the work done in all departments of the Bureau. The editor is Paul C. Freer, M.D., Ph.D., the director of the Bureau of Science, with R. P. Strong, M.D., and H. D. McCaskey, B.S., as co-editors. The subscription price is five dollars, U.S. currency, and the Journal can be obtained from the Director of Printing, Manila, Philippine Islands, to whom remittances are to be sent.

Therapeutics.

Chase, Walter B., finds codein, in $\frac{1}{4}$ gr. to $\frac{1}{2}$ gr. or more given hypodermically, is more satisfactory than morphia after abdominal section.

For the relief of intestinal paresis, salicylate of physostigmina in $\frac{1}{100}$ gr. to $\frac{1}{50}$ gr. dose is recommended by the same authority.

Punjab Veterinary College.

When the Ajmere Veterinary School was closed a short time ago, the students and staff were transferred to the Punjab Veterinary College, and about twenty students joined. In view of the great demand which exists for the services of veterinary assistants trained at the Lahore College, which far exceeds the supply, it was decided to increase the number of students considerably and to improve the standard of education. The extra staff from Ajmere made this practicable and the Local Government has provided the extra accommodation necessary, and a new laboratory and classroom have been built in connection with the segregation ward sanctioned by Sir Charles Rivaz, while a spacious lecture-room and offices for a hospital have also been erected.—*Pioneer Mail*, January 26th, 1906.

Poison in Juar Fodder.

Sir,—In the *Pioneer* of the 13th instant you mention the poisonous effect of juari stalks as a curious thing, but at least in the Northern Punjab and Bar tract this fact is known even to every zemindar child. This phenomenon is limited to droughty seasons in Barani tracts only, and to such fields of well-irrigated areas also which have not been watered from wells. The poison may be prussic acid, but the zemindars think that a kind of very fatal and poisonous worm generates in the stalk, and any animal (cow, bull, buffalo) which eats the stalk certainly dies within an hour or two, but goats do not suffer a bit. To remove the poison, zemindars, after cutting such stalks, sprinkle water over them and then bury them for some hours under blankets. Even a little quantity of rain removes the poison from the standing stalks.—*W. Pioneer Mail*, January 19th, 1906.

The Medical College of Calcutta has received £6,000 out of the lac of rupees presented to the Prince of Wales by the Maharaja of Darbhanga for distribution amongst Indian charities.

A Chair of Colonial Medicine in Paris.

M. Emile Flourens, the ex-Minister and present Deputy for the Department of La Seine, advocates the endowment of a Chair of Tropical Medicine in Paris on the lines of those existing in the Schools of Liverpool and London, and furthermore, that only those medical gentlemen who have obtained the diploma in tropical medicine should be allowed to practise in the Colonies; this much is due to the troops, for whom little has been done; to the officials, for whom still less has been done; and to the natives, who, as a rule, have received nothing in return for their loss of independence.—*L'Europe Coloniale et Diplomatique*, January 24th, 1906.

Ankylostomiasis Prophylaxis.

In Belgium, by the establishment of dispensaries for the miners afflicted with ankylostomiasis, and the payment of 1 franc 50 cents. continued daily until the cure was complete, the disease has been stamped out in five of the largest mines.

Desert Camps: a Proposed Method of Treatment.

Felkin, R. W., holds (*Treatment*, January, 1906) that camp-life in the real desert at a distance from towns gives a genuine mental and bodily rest unobtainable elsewhere. The expenses should not be much more than in a large hotel in a city.

On the evening of December 15 last the first official banquet of the "International Medical Association for the Suppression of War" was held in Paris at the Hôtel Continental.

There were about fifty members present, all of them belonging to the medical profession. The chair was taken by Dr. J. A. Rivière (of Paris), the founder and President of the Association.

The after-dinner speeches were all against war, and great stress was laid on the preponderating part which the medical profession throughout the world, by reason of its influence on Society, is called upon to fill in this work of realising universal peace.

The following gentlemen spoke: Professors Langlois and Richet, Doctors J. A. Rivière, Maréchal, Grellety, Suarez de Mendoza, Mazery, Cogrel, and Bérillon.

Although this Association is only a year old, it already numbers 600 members, all of them medical men, and includes more than 200 professors of all nationalities.

A new German Sleeping Sickness Commission.

The *Medical Weekly* of Berlin announces that Professor Robert Koch has been commissioned by the Imperial Government to proceed to East Africa in order to resume his investigation into the causes of the sleeping sickness. Professor Koch proposes to sail at the beginning of April, and it is understood that he will make Entebbe, in British Uganda, the headquarters for his first series of expeditions. It is anticipated the expedition will last about eighteen months, and £6,000 has been allotted for the expenses of the first year.

As our readers are aware, Professor Koch has already passed some time in East Africa in the study of this and kindred diseases, but in view of the successful work of the English commissions engaged in the investigation of sleeping sickness, there is little beyond matters of detail left for Professor Koch's investigation from the etiological standpoint. On this account the Germans would perhaps have been wiser to have sent some of their admirable economic entomologists to study the question of checking the multiplication of the flies concerned in the transmission of the disease, as this department of the army of science is one in which England is, unfortunately, very short handed; and this most practical question appears at present to be almost untouched.

The more than usually mild winter in Britain contrasts peculiarly with the weather experience in Algiers, where deep snow has fallen, breaking down telegraph lines, blocking the railways and causing great damage to property.

The establishment of a medical school for Burmese is contemplated in Rangoon.

Drugs.

Trypsin in Carcinoma.

Trypsin is being given by many practitioners in Britain at the present moment in cases of carcinoma. Perhaps the best method of exhibition is hypodermically, as all possibility of total destruction of the ferment in the stomach is avoided.

Messrs. Allen and Hanbury, 7, Vere Street, London, W., supply Liquor Trypsin Co. for internal use; Injectio Trypsin Co. for hypodermic use, and Pigment Trypsin Co. for local use.

Malarial Fever and Drugs.

We publish a portion of a letter from Mr. J. H. Niemann, Daly River, Northern Australia, which appeared in the *Chemist and Druggist* of February 3rd, 1906: "Is anything known or published regarding the manner in which malarial fevers modify the normal effects of drugs and of other germ diseases? . . . . I have ascertained from painful experience that belladonna cannot be safely given to any person whose system is impregnated with malaria, except in infinitesimal doses; that the effects of many other drugs are diminished or increased; and have strong reasons for asserting that the benign malaria of North Australia greatly modifies all other germ diseases, if it does not entirely prevent them. The first point, regarding the effect of drugs, is of great importance to the prescriber; the second, regarding the prevention of other diseases, is important to everyone, especially as tuberculosis is included in the list of 'other diseases.'"

We must confess we are unable to make any definite answer to Mr. Niemann on this subject. The suggestion is a novel one, but it is possible, now that the attention of our readers has been directed to the action

of drugs in persons suffering from malarial infection, that some information may be forthcoming from medical men engaged in practice in the tropics.

Books and Papers Received.

PROSTATISM WITHOUT ENLARGEMENT OF THE PROSTATE. By C. H. Chetwood.

Chetwood attributes the signs and symptoms of so-called prostatic irritation when the prostate is not enlarged to contracture of the neck of the bladder, in other words, a fibrous stenosis of the vesical orifice. He does not recommend cutting the stricture, but galvano-prostatotomy through a perineal opening by means of an instrument he has devised. His pamphlet is a reprint from the *Annals of Surgery*, April, 1905.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"American Medicine," January 6, 1906.

MALARIA INFECTION IN KURDESTAN.

Underwood, H. L., considers that in Kurdestan malaria is not only carried by mosquitoes, but also by bed bugs, lice and fleas.

Several species of mosquito, including some Anopheletes, however, occur in Central Asia, and from the point of view of comparative helminthology, any such means of transport of malaria as that suggested is in the last degree improbable.

"Le Nevis Scientifique," November, 1905.

CHOLERA PROPHYLAXIS.

Chantemesse, A., and Borel, F. contend that no person suffering from cholera should be allowed to enter an uninfected country. He should be quarantined, the clothes disinfected, food and drink carefully examined, protection against fly contamination, especially where latrines are defective, and every precaution taken to prevent gastric and intestinal upset.

Such recommendations are, however, of a most reactionary type, and if adopted, would carry us back to the bad old days of quarantine. Modern sanitary practice has shown that, under proper precautions, there is no danger whatever in landing cholera patients, and the adoption of these modern measures have rendered the importation of cholera practically impossible in every country where they have been employed. Quarantine has been abolished by all the more civilized nations because it had proved itself unpractical and inefficient.

"American Medicine," January 13, 1906.

AMERICAN HOOKWORM.

Stiles, C. W., and Goldberger, J., find that the eggs of *Necator americanus* may hatch the rhabditiform embryo in less than twenty-four hours. When the young intestinal stage of the worm is placed on the skin of the back of dogs and rabbits the worm penetrates the skin, and reaches the small intestine in from eight to twelve days.

"Journal of Cutaneous Diseases," January, 1906.

TROPICAL ULCERATION OF NOSE, PHARYNX, AND LARYNX.

Fordyce, J. A., describes a case of ulceration of the upper air passages, which began with an offensive muco-purulent discharge from the nose. The nose enlarged and ulcerated, the septum necrosed, the uvula disappeared, and the soft palate presented a worm-eaten appearance; the tongue became atrophied at the base, and the pharynx and larynx showed ulcerations and old cicatrices.

A condition similar and probably identical with the case described was met with by Dr. W. F. Arnold at Guam in 1902. Dr. Arnold found 5 per cent of the population of Guam suffering from this ailment. The disease is neither tubercular nor syphilitic. Breda has described analogous ulcerations amongst Italians returned from Brazil, and named by him *Frambœsia Brasiliana*, or Boubas.

The above is of interest in connection with the paper on "Rhino-pharyngitis Mutilans," by Surgeon J. E. Leys, M.D., U.S. Navy, published in another column, as it seems probable that both papers refer to the same condition.

"Boston Med. and Surg. Journal," January 11, 1906.

MALARIA IN THE PHILIPPINES.

Chamberlain, W. P., from the study of 120 cases of malaria in Camp Gregg, Philippines, concludes that (1) large numbers of anopheles increase the malarial index; (2) Quartan infections were infrequent; (3) Œstivo-autumnal infections were remittent 35 per cent., quotidian intermittent 25 per cent., tertian intermittent 30 per cent.; (4) no distinctive parasites were recognised in the æstivo-autumnal infections.

"Nature," January 4, 1906, p. 235.

INSECTS AS CARRIERS OF DISEASE.

Shipley, A. E., F.R.S., publishes an address to the British Association at Pretoria under the above title. From the nature of the occasion it can hardly be expected to contain any information that has not appeared in these columns, but it forms, nevertheless, a most convenient and up-to-date *resumé* of our knowledge on the subject, which may be consulted with advantage by any one requiring a handy reference paper on this question.

"Indian Med. Gazette," January, 1906, p. 7.

THREE DAYS' FEVER OF CHITRAL.

McCarrison, Captain R., I.M.S. The author describes his paper as a contribution to the unclassed fevers of India. As may be gathered from the title the attacks are short, but they are also sharp, the principal subjective symptoms being bone-aches and frontal headache.

Though hitherto returned as such, the disease is not malarial, as the blood contains no parasites, either protozoal or bacterial. It can hardly be influenza, as, though seasonal, it is confined to the hotter times of the year, coinciding with the mulberry harvest. It is not contagious, though houses and places become infective, so that the disease can only be acquired by visiting them. Those who have suffered are immune to subsequent attacks. Quinine is useless, either remedially or as a prophylactic, and treatment resolves itself into measures to diminish the patient's discomfort, such as sponging and douching.

Many years ago the writer met with exactly similar cases in Natal, and indeed suffered in his own person. At that time the cases were locally known to the profession as "dengue," and were, he believes, usually returned as such.

The uniformly rapid and complete recovery, however, made any such a diagnosis quite untenable, so that personally he returned them as "febricula," for want of any better term.

He feels, however, little doubt as to the identity of the clinical pictures, and it is to be noted that Captain McCarrison, while rejecting the diagnosis, remarks on its similarity to dengue.

We should like to hear from our readers in Natal and Zululand whether such cases are still met with there, and would in such case draw their attention to the circumstance that Captain McCarrison evidently suspects sandflies of being the transmitting agents of the disease, and so suggests the prophylactic use of mosquito nets.

"Revista de Med. y Criug," Vol. ix., No. 22, 1905.

ANAKHRE OR GOUNDOU.

Ayala, A., Havana, reports a case of goundou occurring in Caracas, Venezuela, in a white man, aged 39. The growth on either side of the nose was symmetrical. The man was otherwise quite healthy.

"Reforma Medica," August 12, 1905.

SUBFEBRILE TEMPERATURE OF ANKYLOSTOMIASIS.

Gabbi, W., states that slight elevations of temperature are present in ankylostomiasis. This state, which he terms "subfebrile," is present in severe cases only. The elevation in temperature is irregular, there is either an evening rise, an intermittent, or an irregular subcontinuous type. Caliri finds albumose present in the blood of persons with ankylostomiasis, and believes that it is the presence of albumose in the blood which determines the rise in temperature.

"Quarterly Journal Microscopical Science," November, 1905.

OBSERVATIONS ON HÆMATOZOA IN CEYLON.

Castellani, Aldo, and Willey, A., state they discovered in human blood fine "vermicules" of crescentic form, rather longer than the diameter of a red corpuscle, characterised by the absence of pigment and presence of vacuoles. The specimens were taken from a case of "fever," which showed no malarial parasites and a negative Widal reaction, and are not at all unlike certain known trypanosomes in certain stages of development. Similar bodies were found in the finger blood of fever patients, and the authors do not appear to consider them as freed and altered "crescents," or as necessarily connected with malarial parasites at all. Similar bodies were found in a babbling thrush and in the Indian crow.

"C. R. Soc. Biologie," T. lix., pp. 240-245.

SERUM DIAGNOSIS OF MEDITERRANEAN FEVER, &c.

Nicolle, C. employs for serum diagnosis cultures of the *B. melitensis*, three to six days old, on ordinary gelose, emulsified without preliminary grating in physiological water or bouillon. The suspected serum is added to this in the proportion of $\frac{1}{2}$, $\frac{1}{5}$, $\frac{1}{10}$, $\frac{1}{20}$, $\frac{1}{50}$, and $\frac{1}{100}$, in small test tubes, and the examination is made after sixteen to twenty hours. When distinct agglutination, to the naked eye and under the microscope, is obtained in $\frac{1}{10}$ dilutions, he considers that the diagnosis of Malta fever may be taken as proved.

In the second paper he records the results of the application of Wright's serum reaction to the cases of thirty-five patients affected with various other infections, and shows that serum drawn from them had little or no agglutinating action on the *B. melitensis*.

In collaboration with M. Hyat, in the same publication, he gives results showing the value of the procedure in actual practice.

In five cases, which were ultimately proved not to be instances of Malta fever, the action was negative, while in thirteen others, which presented throughout the clinical picture of Malta fever, it was positive.

The leucocyte formula of Malta fever is an intense mononucleocytosis amounting to 80 per cent. of mononuclear cells.

"C. R. Soc. Biologie," T. xix., pp. 302-304.

DIAGNOSTIC VALUE OF POLYNUCLEAR HYPERLEUCOCYTOSIS OF BLOOD IN TROPICAL ABSCESS OF LIVER.

Khouri, J., out of ten cases examined, found the number of leucocytes was normal in one, subnormal in four, while three showed moderate, and three pronounced leucocytosis. From this it is evident that the symptom or its absence is of little or no diagnostic value.

"Amer. Naturalist," xxxix., pp. 601-724.

THE INTERRELATIONSHIPS OF THE SPOROZOA.

Crawley, H., regards the relationships between the subclasses *Telosporidia* and *neosporidia* as vague, so that the class, taken as a whole, may not even belong to a single phylum. Amongst the Telosporidia he regards the gregarines as the most primitive form, and, amongst the latter, the polycystids. M. F. Mesnil, the well-known protozoologist, commenting on this paper in the current *Bulletin de l'Institut Pasteur*, notes that Crawley ignores the now well-recognised intestinal monocystids, and states his opinion that it is amongst these that the ancestral form should be sought. Both, however, are agreed in considering the Shigogregarines as derived from the Engregarines. He looks upon the Coccidia and the Hæmocytozoa as closely allied, and so approves of Doflein combining them under the title of Coccidiomorpha.

"C. R. Soc. Biologie," lix., p. 308.

ABSORPTION OF TUBERCLE BACILLI BY FRESHLY SHAVEN SKIN.

Nouri, Osman (Inst. Bacter., Constantinople), shaved the inguinal region of guinea-pigs, and then rubbed them with absorbent cotton, fouled with tuberculous sputum, with the result that the corresponding lymphatic glands became swollen in eight to fifteen days, and the animals died in from thirty to fifty days.

This is hardly pleasant reading for those who do not shave themselves, and, in view of the rudeness of of the tonsorial art in Mahommedan and other countries where the victim is scraped with a blunt razor, moistened with water, which the operator not unfrequently supplements, in awkward corners, with saliva, may account for the puzzling location of certain tubercular lesions occasionally met with in such countries, where the portions of the body habitually shaven are much more extensive than is anywhere the case in Europe.

"Centralb. für Bakt. Parasiten. u. Infektionskrank," xxxix., pp. 610-613.

A NEW, CERTAIN, AND HARMLESS METHOD OF IMMUNISATION AGAINST PLAGUE.

Huetope, F., and Kiruchi, J., by experiments based on those of Bail, show that an "agressine" effective against plague can also easily be obtained. A single injection prolonged the life of animals subsequently inoculated with plague, and a second infection enabled them to resist the action of an infection surely fatal to controls, always provided that the inoculation be not practised too soon after the second, in which case the morbidity of an infection is not diminished but enhanced.

They accordingly claim to be the first to devise a sure and harmless plan of immunisation.

"Ann. Soc. Entom.," Paris, lxxiv., pp. 20-28.

EGG DEPOSITION AND THE LARVAL LIFE OF THE TABANIDÆ.

Legaillon, A. As the Tabanidæ are implicated in the transmission of trypanosomes, the author's observations on *T. quatuornotatus*, Meig., possess a special interest for our readers.

The eggs are laid in bunches in places that may be either dry or moist, for instance, on the leaves of plants, and are at first white, but soon darken. As is already known, some

larvæ may be aquatic and others terrestrial, and that their habits are carnivorous. The eggs of the species under consideration hatched out in fourteen days (in June), and are white and transparent.

They feed on dead prey and on organic detritus, and perhaps even on sluggish living animals.

They can live under varied conditions of moisture, and even in water. Further observations are promised.

Personal Notes.

R.A.M.C.

Embarkations. — For India: Lieut.-Cols. B. J. McCreery and J. M. F. Shine; Majors T. W. Gibbard and H. A. Hinge; Lieuts. J. Campbell, W. H. Hills, J. P. Lynch, W. G. Maydon, and L. V. Thurston. For Mauritius: Lieut.-Col. A. Peterkin; Capt. C. S. Smith; and Lieuts. P. Power and C. S. Wallace. For Malta: Major C. C. Fleming, D.S.O., and Capt. H. S. Anderson. For West Africa: Major G. T. Rawnsley and Capt. J. McD. McCarthy.

Ceylon (November 1, 1905).—Lieut.-Col. R. D. Hodson, Capt. L. M. Purser, and Capt. T. B. Unwin, R.A.M.C., are under orders for England, tour expired, and will probably leave Ceylon on January 3rd, 1906, in His Majesty's transport *Dunera*. Lieut.-Col. G. H. Sylvester, Capt. E. C. Hayes, and Lieut. C. R. Miller, R.A.M.C., are expected by the same boat on November 30th, 1905.

Lieut.-Col. G. H. Sylvester, R.A.M.C., takes over the command of the Royal Army Medical Corps and Senior Medical Officer of the Troops in the Ceylon Command. Capt. E. C. Hayes and Lieut. C. R. Miller, R.A.M.C., will be stationed in Colombo, the former performing the duties of Sanitary Officer in addition to ordinary duty.

Sierra Leone.—Capt. H. W. Grattan, R.A.M.C., writes (November 24th, 1905): Capt. W. H. S. Nickerson, V.C., arrived on November 23rd, for a tour of service.

Simla (*India*).—Capt. E. Blake Knox, R.A.M.C. Secretary to the Principal Medical Officer, His Majesty's Forces in India, writes (November 23rd, 1905):—

"*Appointments.*—Lieut.-Col. A. W. P. Inman, M.B., R.A.M.C., to officiate as Principal Medical Officer, 8th (Lucknow) Division, *vice* Col. G. D. N. Leake, R.A.M.C., granted leave out of India. Lieut.-Col. J. R. Dodd, R.A.M.C., to officiate as Principal Medical Officer, Bareilly and Gharwal Brigades, *vice* Col. G. J. Kelly, I.M.S., appointed to officiate as Principal Medical Officer, 7th (Meerut) Division. Col. H. R. Whitehead, R.A.M.C., to officiate as Principal Medical Officer, 2nd (Rawal Pindi) Division, *vice* Col. B. M. Blennerhassett, C.M.G., R.A.M.C., granted six months' sick leave out of India. Lieut.-Col. D. O'Sullivan, R.A.M.C., to officiate as Principal Medical Officer, Abbotabad and Sialkot Brigades, *vice* Col. Whitehead, R.A.M.C., transferred to Rawal Pindi temporarily. Lieut.-Col. D. O'Sullivan has also been confirmed to the Command of the Station Hospital, Rawal Pindi, with effect from November 4th, 1905. Capt. W. R. P. Goodwin, R.A.M.C., to be Personal Assistant to Principal Medical Officer, Northern Command, *vice* Capt. E. T. F. Birrell, R.A.M.C., vacated. Lieut. S. C. Bowle, R.A.M.C., to be Dental Specialist in Western Command."

Singapore (*Straits Settlements*). — Lieut.-Col. W. Dick, R.A.M.C., writes (November 2nd, 1905): "The following officers are tour expired. Lieut.-Col. W. Dick, Major J. H. E. Austin, and Capt. G. F. Sheehan. Notification has been received that these officers are to be relieved in December by Lieut.-Col. H. H. Johnson, C.B., Major C. B. Martin, and Lieut. G. A. D. Harvey. Major J. Ritchie, who was also tour expired, has been permitted to extend his service in Singapore for another year."

The services of Capt. J. Tobin, R.A.M.C., on the Aden Boundary Commission, have been brought to the special notice of the Commander-in-Chief.

Indian Medical Service.

Major Molesworth, I.M.S., Captain Vane and Captain Popham, now on Lord Ampthill's Staff, have been appointed to serve on the Staff of Sir Arthur Lawley, the Governor-designate of Madras.

Major E. R. Parry, M.B., I.M.S., is appointed temporarily to be Superintendent of the Dacca Central Gaol, *vice* Mr. W. A. C. Beadon, retired, with effect from the date of receiving charge of the office.

The services of Captain A. C. MacGilchrist, M.B., I.M.S., are placed at the disposal of the Government of India in the Home Department.

Captain W. D. Ritchie, M.B., I.M.S., Civil Surgeon, is posted to Jalpaiguri.

Major J. S. S. Lumsden, I.M.S. Civil Surgeon, Bahraich, furlough on medical certificate for one year, from December 23rd.

Consequent on the death of Honorary Captain G. McCall, I.S.M.D., Civil Surgeon, Babu Kedar Nath Bose, Officiating Civil Surgeon, Jaunpur, to be confirmed as a Civil Surgeon.

To be Major: Captain Hugh Bennett, M.B., F.R.C.S.E.

Sanitary—Plague.

Lieutenant-Colonel W. B. Bannerman, M.D., I.M.S. (Madras), Director, Plague Research Laboratory, Parel, is granted privilege leave for three months, with effect from November 18th.

Captain G. Lamb, M.D., I.M.S. (Bengal), is appointed to officiate as Director of the Plague Research Laboratory, Bombay, during the absence on leave of Lieutenant-Colonel W. B. Bannerman, M.D., I.M.S., in addition to his special duty under the orders of the Sanitary Commissioner with the Government of India.

Department of Revenue and Agriculture.

Mr. R. E. Montgomery, M.R.C.V.S., Civil Veterinary Department, is appointed with effect from December 8th, 1905, to make, under the orders of the Inspector-General, Civil Veterinary Department, a special investigation into the diseases of camels.

Colonial Medical Service.

Dr. W. T. Kergin, of Port Simpson, British Columbia, has taken over the duties of a Medical Health Officer in that Province of the Dominion.

Fry.—The selection of Dr. W. H. Fry, Colonial Surgeon of Province Wellesley, North, Straits Settlements, for the office of State Surgeon of Pahang, Federated Malay States, has been approved by the Secretary of State.

Purchas.—Dr. F. A. G. Purchas, District Medical Officer for Newport, Manchester, Jamaica, has been transferred to Swanswich Trelawny, in place of Dr. C. T. Dewar, who has retired from the service.

The offices of Dr. E. H. Bannister and Dr. J. W. Hawkins as Health Officers for the Port of Bridgetown, Barbados, have been abolished on the coming into operation of the new Quarantine Ordinance. Both officers receive gratuities.

Dr. J. White Hopkins, Assistant Medical Officer, Sarawak, acts as Principal Medical Officer and Superintendent of Indian Immigrants during the absence on leave of Dr. A. J. G. Barker.

Dr. F. O. Stedman has been made a Member of the Medical Board of Hong Kong, and will serve as Secretary of the Board in place of Dr. Alexander Rennie, who has resigned.

Dr. Alexander Rennie has permanently retired from practice in Hong Kong.

Dr. Smartt has arrived in England from British Guiana.

Dr. Ireland has arrived in England from Trinidad.

Commercial Corporations.

Baggs.—Dr. J. G. Baggs has been appointed Medical Officer to the Para Electric Railway and Lighting Co., of Brazil, and leaves England about February 1st.

Domestic.

Macnicol.—At the Medical Mission House, Kalna, Bengal, on January 20th, 1906, the wife of the Rev. Malcolm Macnicol, M.B., C.M., of a son.

Illius—Ford.—At St. John's Church, Calcutta, on December 30th, 1905, by the Rev. C. R. T. Winckley, Henry Warwick Illius, Capt. I.M.S., to Frances Elsie, younger daughter of the late Matthew and Mrs. Ford.

PLAGUE.

Prevalence of the Disease.

		Cases.	Deaths.
India.—Week ended	Dec. 9th...	—	3,075
,,	,, 16th...	—	3,247
,,	,, 23rd...	4,182	3,170
,,	,, 30th...	5,184	4,278

South Africa.—No plague up to January 20th, 1906, in any part of South Africa since November 18th, 1905, when one case was reported in Port Elizabeth.

Rats and mice were still found plague-infected in Port Elizabeth on January 20th.

		Cases.	Deaths.
Mauritius.—Week ended	Jan. 5th...	4	4
,,	,, 12th...	4	3
,,	,, 19th...	1	1
,,	,, 26th...	1	1
,,	Feb. 2nd...	2	1
,,	,, 9th...	1	0

		Cases.	Deaths.
Hong Kong.—Week ended	Jan. 3rd...	2	2
,,	,, 6th...	2	2
,,	,, 10th...	6	6
,,	,, 27th...	1	1

Persia.—Plague prevailed in the Maisar district of Seisan on January 22nd.

		Cases.	Deaths.
Zanzibar.—Week ended	Oct. 14th...	15	8
,,	Nov. 4th...	12	—

Egypt.—Case of plague reported in Alexandria on November 7th.

Australia.—No fresh cases of plague in Queensland since September 14th. As late as December 20th, 1905, plague-infected rats were found in the neighbourhood of Darling harbour.

Sydney.—Nine cases of plague occurred on a French mail steamer which called at Sydney, and infected rats were found on board the vessel.

Brazil.—From January 1st to October 22nd, 1905, there were 91 deaths from plague in Rio de Janiero.

Madeira. — The report that plague existed at Madeira is contradicted.

The Campaign Against the Rats in Rangoon.

The total number of plague cases for December was 98, with 91 deaths, against 113 cases and 110 deaths during November. The incidence of the disease was heaviest among the low-class Hindu population. One hundred and thirty-two rats were examined, of which 27 were found infected with plague. Fourteen thousand six hundred and sixty-six rats were destroyed during December. Although the total number of cases was less in December than in any previous month since the outbreak of the epidemic in February last, yet no quarter of the Municipality was free from the disease during the whole month. No case is reported from Cantonments. The centres of the infection appear to be widely scattered throughout the municipal area, and there is no indication that the disease has been stamped out in any locality.—*Pioneer Mail*, January 12th, 1906.

Plague Researches.

(1) M. Herzog, from experience of plague gained in the Philippines, finds a hyaline fibrin thrombosis in the glomeruli of the kidney; in *post-mortem* examination of seven out of twenty cases of plague, Dr. Herzog believes that plague is not a true septicæmia, but a local lymphatic infection, and that the universal dissemination of the infecting bacilli through the blood current generally only occurs during the agonal stage.

(2) R. P. Strong has succeeded in preparing a vaccine against plague. He uses the living plague organisms in his protective inoculations. So far, the experiment has proved successful in rats.—*Manila Medical Society*, November 22nd, 1905.

Reviews.

PATENT FOODS AND PATENT MEDICINES. Two lectures. By Robert Hutchison, M.D., F.R.C.P. Second edition. John Bale, Sons and Danielsson, Ltd., Oxford House, 83 - 91, Great Titchfield Street, Oxford Street, London, W., 1906. Price 1s. net.

It is time some one spoke out freely about patent foods and patent medicines, and Dr. Robert Hutchison has done so in fearless terms. Some of his remarks are most telling and express what every medical man, who thinks at all, must have frequently wished to express. He says, "most patent foods exist because certain persons have found that it pays to produce them"; and, we might add, the benefits they bestow upon the public are confined to those few who profit by the production of the articles. The further statement that of the patent foods "not one of them is worth the money asked for it," is an expression of opinion with which every medical man will coincide; and that it is merely the fact that patients will more readily listen to their doctor when he advises patent foods, in place of simple foods prepared at home, that any medical man would ever think of recommending them. The honesty of the doctor is thereby strained, but as he has to live he, calling it tact, agrees with the patient's desires. In regard to patent medicines, Dr. Hutchison shows that they are compounded for the most part of the usual pharmacopœial drugs in ordinary use, and attributes their reputation to "persistent and audacious advertisement." Belief in quackery and patent medicines is "as rife, nay, I venture to say is more rife, in Belgravia than in Bethnal Green," so that so-called education has nothing to do with their belief in the efficacy. These lectures should be read by every practitioner at home and abroad, as he will be thereby better able to guard his patients against the patent food vendor, who is destroying the health and emptying the pockets of a credulous public, and to stem the influence of quackery, which tends to react deleteriously upon the character of the people of any nation. One means of obtaining "certificates of cure" Dr. Hutchison has not told us, it is this: An agent for a patent medicine finds out from a tradesman those of his customers who owe him money. He buys the bad debts for a small sum, proceeds to the houses of these customers and informs them that if they will take his medicine for a week, and at the end of the week state that the medicine has done them good or cured them, he will pay the bill they owe to the tradesmen. This method of obtaining evidence of cure needs no comment, but it is one which was told in the public press lately.

EXAMEN DE 43 CAS DE PALUDISME PROVENANT DE RÉGIONS TROPICALES (An Examination of 43 Cases of Malaria from Tropical Regions). By Surgeon-Major A. Billet, Chief of the Bacteriological Laboratory at the Military Hospital at Marseilles. Extract from the Minutes of the Societe de Biologie. (Meeting held on November 25th, 1905.)

During the year 1904-1905, Dr. Billet was able to make notes on 43 cases of malaria which came from the Tropics, viz., Madagascar, Tonkin, Senegal, Ivory Coast, and the Soudan. They were divided as follows:—

(1) *Primary tertian* ague, simple or double, characterised in all cases by small schizonts, annular, slightly or not at all pigmented, with crescents. Endogenous forms of multiplications rare or even absent in the circulation. Schüffner's dots scanty. (20 cases.)

(2) *Secondary tertian* ague (chronic), simple or double, characterised by large schizonts, amœboid, black pigment abundant, rounded gametes. Endogenous forms of multiplication, with from 16 to 20 merozoites. Schüffner's dots plentiful. (18 cases.)

(3) *Quartan* ague, characterised by pigmented schizonts, smaller than those of secondary tertian type, and by gametes, also rounded, but smaller. Segmentation forms show eight merozoites at most. No Schüffner's dots in the infected blood cells (5 cases).

According to Laveran both the small and the large forms belong to the same pathogenic agent. Dr. Billet verifies this assertion, inasmuch as it applies to the tertian type of ague, which is more commonly found in the French colonies generally; in fact, he quotes four cases where he was able to study the transformation of the small tertian parasitic rings into large pigmented parasites of the same type of malaria, which he designates as secondary ague.

He considers the parasite of quartan ague as belonging to a distinct species from that of tertian ague. He was only able to observe crescents in two authentic cases of quartan ague.

WITH THE ABYSSINIANS IN SOMALILAND. By Major J. Willes Jennings, R.A.M.C. (Hodder and Stoughton.)

Although in no sense a medical work, but a well-written and breezy book of travel, this book will be interesting to all our readers as a lively illustration of the evidences of the field of adventure and interest open to those who follow up the profession of medicine in tropical lands. Major Jennings was in medical charge of the little knot of British officers who were attached to the Abyssinian Army which co-operated with us against the much misnamed "Mad Mullah"; and his adventures make pleasant reading, and convey to the reader in excellent colloquial English a vivid idea of the country and its primitive inhabitants.

Those who have shared in similar expeditions will not be surprised to find Major Jennings devoting more of his time to veterinary surgery than to human

medicine, for the Abyssinian soldiers proved so healthy as to seldom require any other treatment than an occasional dose of male-fern, while the efficiency of the transport animals depended greatly on his scientific and devoted attention.

As might be expected, however, the book is by no means devoid of interesting medical observation. He notes, for example, how ill the fish-eating theory of the causation of leprosy fits in with the facts of the case in Abyssinia, where there are some 8,000 lepers who can rarely, if ever, have eaten fish, owing to the scarcity of the article in a country where "during the greater part of the year many of the wells do not contain water, much less fish." His remarks on the enormous practical sanitary value of tropical sunlight are also interesting, as he doubts if the inhabitants of the terribly insanitary Abyssinian towns could survive at all but for the "merciful dealings of a tropical sun, which can well-nigh convert the smell of a pole-cat into the aroma of a nosegay." His instance of the disappearance of cholera effected by removing troops from a warm, damp, shady site, to a bare, breezy, tropical plain, is most instructive. He notes, too, that the greater part of Abyssinia is practically free from malaria.

It is mainly, however, as a book of travel and adventure that the book is to be commended, and from this point of view it is one of the best that has appeared for some time.

THE REVIEW OF HUGGARD'S HANDBOOK OF CLIMATIC TREATMENT.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

SIRS,—While thanking you for the favourable notice of my *Handbook of Climatic Treatment* in your issue of January 15th, may I be allowed a word of comment?

The reviewer says "there are occasional errors, as, for example, the explanation of the comparative coldness of the upper layers of the atmosphere, which is said to be mainly due to the physical law of the expansion of gases." Now this law explains only the rather exceptional case of up-hill winds, but the absorption of heat from expansion under these circumstances would rapidly be replaced by the sun's rays, were it not for the true reason, which is the universal operation of the law of selective absorption. Air, whether dry or wet, is very transparent to short-wave rays, but absorbs the long, dark heat waves, such as are radiated by the ground, and therefore acts in the same way as the glass of a green-house, forming a sort of heat-trap. The more dense the atmosphere, the more efficient it is in this respect, and hence naturally the rarer upper regions, being less efficient heat-traps, do not trap as much heat.

"Moist air is a much better trap than dry air, but this does not affect the explanation, as under any circumstances

the upper layers would be to a greater or less extent cooler."

On going again through the literature touching the point, I find that the account given on pp. 17 and 18 of my book states and explains the facts with perfect accuracy, though in a very condensed form. The supposed "error" is the teaching to be found in every treatise on the subject. Loomis (*Treatise on Meteorology*, New York, 1892, p. 41), says: "This decrease of temperature as we rise above the earth's surface is mainly due to the expansion of the air." A. Buchan, in his *Introductory Text-Book of Meteorology* (1871, p. 76, paragraph 208); R. H. Scott in his *Elementary Meteorology* (4th ed., 1887, p. 213); F. Waldo in his *Modern Meteorology* (1893, pp. 208-216); Julius Hann in his *Lehrbuch der Meteorologie* (Leipzig, 1901, pp. 161 and 748-752); Wilhelm Trabert in his *Meteorologie und Klimatologie* (Leipzig und Wien, 1905, pp. 47-48), all give the same explanation.

The reviewer's "true reason, which is the universal operation of the law of selective absorption," explains, contrary to what the reviewer supposes, not the comparative coldness of the upper layers of the atmosphere, but only why the rate of cooling in the lower layers of the atmosphere is not determined wholly by the law of expansion of gases (Hann, *Handbuch der Klimatologie*, 2nd ed., 1897, vol. i., pp. 121 and 261; W. Trabert, *op. cit.*, pp. 21-22.)

In regard to very elementary facts I must confess I had not thought bibliographical references needful.

Through a printer's error a minus sign is omitted on page 47 of the book. The half sentence quoted should run: "the black-bulb thermometer registered 55·5°C., whilst at the same time the temperature of the snow in the shade was −5·6°C." The absence of the minus sign doubtless warrants the reviewer's supposition that the observer referred to the air over the snow instead of to the snow itself.

Trusting that you will be able to find space for this rather long comment,

I have the honour to be, sir,
Your obedient servant,
WILLIAM R. HUGGARD.

Davos Platz, January 4th, 1906.

[The criticism in question was based, as a matter of fact, on Hann's standard work, quoted by Dr. Huggard, and the following extract from Dr. Ward's excellent translation of Hann (p. 265), will be seen affords ample justification of the criticism :—

"*Causes of the vertical decrease of temperature.*—The facts of the vertical decrease of temperature have now been considered. It remains to give an explanation of them. It was noted at the close of the chapter on Solar Climate (Chapter VI.), that the storage of heat at the bottom of the atmosphere results from the peculiar behaviour of this atmosphere toward solar radiation. This process has been called *selective absorption*. The radiations of shorter wave-length, including the luminous rays, are less absorbed, but more scattered, while the radiations of greater wave-length—the invisible infra-red rays—suffer a greater selective absorption, and are to some extent altogether prevented from reaching the earth's surface. As solar radiation is very rich in rays of such wave-length as are readily transmitted by the atmosphere, a large proportion of this radiation is available for warming the earth's surface. On the other hand, the 'heat rays' which are emitted from the earth's surface are to a very considerable extent absorbed by the atmosphere, because this is non-luminous radiation, of long wave-length, in the extreme infra-red portion of the spectrum. Thus it is seen that the radiation from the sun passes to the earth's surface through the atmosphere more freely than the non-luminous radiation from the earth passes out again through the atmosphere. In this way, the atmosphere helps to store up heat at the earth's surface, and this process of storage is naturally most effective in the lower strata, which are the densest and contain the most impurities, and is least effective in the rare, dry, and clean air of greater altitudes.

"Therefore the thinner the atmospheric envelope, the less the effect of the atmosphere, and the lower the temperature of bodies within it, which are then exposed to a freer receipt and loss of radiant energy. The mean temperature of the air must be distinguished from that of the surface which the atmosphere protects. The air temperature decreases with increase of altitude, in spite of the increase in the intensity of solar radiation with the corresponding decrease in the vertical thickness of the absorbing envelope. Exception must be made, however, in the case of an elevated zone of incipient absorption, for which the vertical temperature gradient is nearly zero."

The remark as to the scantiness of bibliographical references referred to the book generally, and certainly not to its treatment of "elementary facts."]

THE REVIEWER.

DR. HARTINGTON'S ARTICLE ON FIT AND UNFIT PERSONS.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

SIRS,—It was with much surprise that I read in page 16 of your Journal, dated the 15th inst., in Dr. Hartigan's article "On Fit and Unfit Persons for Residence in Warm Climates," the following words, "I have purposely excluded the Reviera, having found its climate lowering, treacherous, and changeable, many of its popular resorts insanitary (in flies and smells they could favourably compete with 'Eastern Bazaars' or 'China towns'), whilst, when the mistral blows, the dust is most irritating to delicate throats and bronchi; the sun and sky give them their only advantage over our cloudy land."

This wholesale libel on a number of popular health resorts, both in France and Italy, ought not to pass unrefuted in the forthcoming numbers of your Journal.

I fear that your eminently useful and able periodical is not much read in the Reviera winter resorts, otherwise I am sure you would receive many a protest from the dozens of British doctors, who, like myself, come to this delightful climate year after year on account of its salubrity and other advantages.

As I have visited most of the coast towns between Marseilles and Genoa, and have resided also some years in Western India, I can safely assert that nowhere is there a Reviera town, frequented by invalids, that could, "in flies and smells, favourably compete with 'Eastern Bazaars,' or 'China towns'." Furthermore, I would say that as regards sanitation most of the Reviera health resorts would compare quite favourably with our British watering places. I do not pretend that every town on this coast is as sanitary as it might be. I have yet to meet the Medical Officer of Health in our own land who is fully satisfied with the sanitation of his district.

The thousands of elderly persons and invalids that come out every season to the brightness and beauty of this coast, thereby loudly attest to the advantages they derive from being free from fogs, frosts, and other failings of our less favoured land. Is it likely that these visitors to the sunny south would banish themselves from their homes and friends, incurring thereby no small expense, if, as Dr. Hartigan says, the climate was lowering, treacherous, and changeable ?

No one is likely to find a perfect winter climate, but for accessibility from Great Britain, for salubrity, warmth, and many other advantages, I know of none equal to that of the Riviera, and I often flatter myself that I have chosen one of the best of the North Mediterranean resorts.

I know something of most of the chief resorts of Italy and Sicily, but have found no climate equal to that of San Remo.

I could add much more, but forbear to burden your columns any further.

I am, &c.,
W. SOLTAU ECCLES.

Hotel Bel Sito, San Remo, Italy.
January 31*st*, 1906.

ZAMBESI ULCER.

TO THE EDITORS OF THE "JOURNAL OF TROPICAL MEDICINE."

SIRS,—Having just started to read an accumulation of your Journals, I now notice under "Zambesi Ulcer," by Z. E. Ashley-Emile, in the number of September 15th, 1905, a description of common ulcers of the leg, met with in Southern Tropical Africa, of which the writer claims to have discovered the cause in the following words among others, *viz.*, "I may, then, lay claim to the unique distinction of being first in the field in bringing to notice the cause of these ulcers, which has hitherto remained in obscurity, and evaded elucidation by many eminent observers in tropical medicine who have resided in Zambesia." So far as I can recall, the only eminent observers who have resided in that part of the world were the members of the Royal Society's Commission on Blackwater Fever, and it is not likely that they paid any particular attention to this question. The writer may have been the first to describe these ulcers, I don't know, but as to a larva not being known to be a cause of some of these ulcers, and that the point had hitherto remained in obscurity, I must say that I think he has not a wide experience of that part of Central Africa, and of the medical men there. The attacks of this larva are well-known to all, and Europeans frequently get their boys to extract them. I have been asked to extract one from the glans penis. I have a specimen I mounted on a slide, north of Lake Nyassa, over five years ago, and among those who have seen it are Professor (now Sir John) MacFadyean. At the same time I got a native to catch some of the parent fly, and kept a dozen of them in paper for two years, but when I reached England they were too much damaged to be of any use for identification. The common sites for Europeans to be attacked are the various parts of the trunk, and I have taken them from the back of the hand. They are believed to adhere to clothes that have been dried on the grass. I thought it more than likely that specimens of these larvæ had been taken home to the Tropical School by such men as Dr. Daniels. The larva appears to resemble the one the writer quotes as described by Blanchard, and as he has not proved that it is not identical, how can he claim to have discovered it?

The advice with reference to boots, leggings, long grass and houses is unpractical and would not be followed; men desire comfort and convenience in these matters at home, and a sportsman cannot avoid long grass; besides, the larva is not such a pest as to require disinfection of the floors.

Finally, I do not think that the majority of ulcers in the situation he describes are started by this larva; natives will generally say they were caused by a knock from a tree-stump. Common ulcers of the legs in Europeans have also been known as "fever sores"; some microscopical work is required on the subject.

I am, Sirs,
Your obedient servant,
J. E. S. OLD, M.R.C.S.Eng.

Aden, February 1st, 1906.

BERI-BERI IN SYLHET, ASSAM.—During the last week of October, 1905, cases of beri-beri occurred in the Sylhet Gaol, and by November 8th 100 cases had occurred with 8 deaths. The deaths are stated to have occurred amongst those of the convicts engaged at the oil mills, which are said to be insanitary. A more liberal diet and improved hygienic environment lessened the number of cases.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communications.

TICK FEVER.

By Philip Ross, M.D.

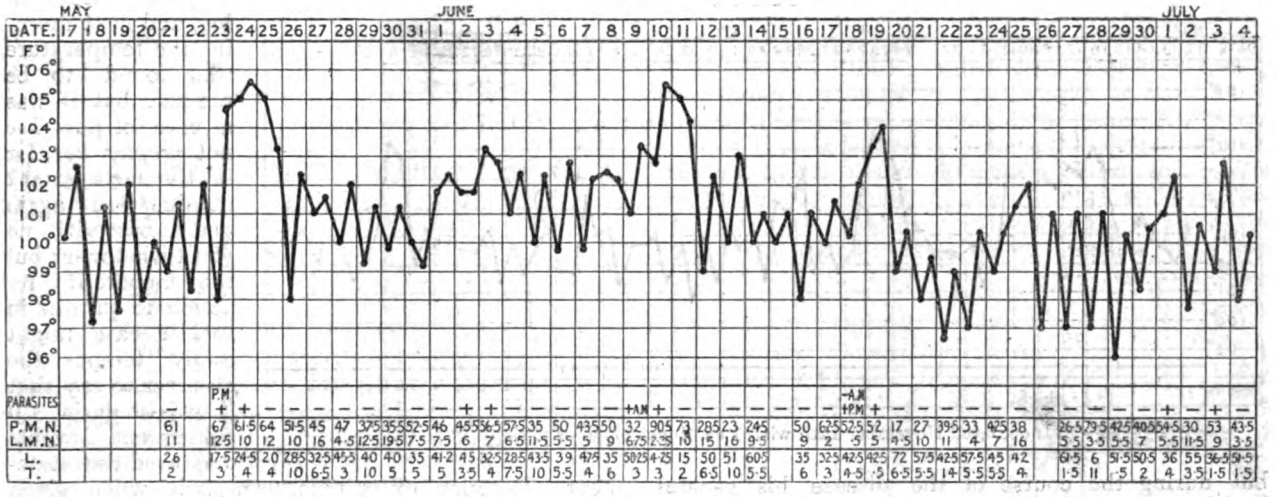
Definition.—Tick fever of Uganda is a specific fever due to the presence of a spirochæte in the general circulation. This spirochæte is conveyed by the bite of a tick (*Ornithodorus*), but is also communicable by inoculation with infected blood.

History.—Fever due to the bite of a tick, *Argas moubata*, probably an ornithodorus, was first described by Dr. Livingstone. Since this description there seems to have been very little written on the subject. Manson, in his "Tropical Diseases" (1), quotes from Sir John Kirk, and from letters from Dowson and Daniels. More recently Christie suggested that the disease might be due to *Filaria perstans*, inoculated by the bite of an ornithodorus, but the general opinion, as shown by the discussion following a paper by Nuttall at the Epidemiological Society towards the end of 1904, seems to have been that the disease was probably a piroplasmosis. Towards the end of 1903 I found spirochætæ in a case of fever under the care of Dr. Hodges at Entebbe (2), and succeeded in infecting a monkey from this case. Within a few weeks Cook, of the C.M.S. Hospital, Mengo, also found spirochætæ in a fever patient. This latter writer had probably seen but not recognised the organism some two years before.

Nuttall had previously suggested that the spirochæte of relapsing fever might be conveyed by such insects as bed-bugs, and in September, 1903, Marchoux and Salimbeni (3) described the spirillosis of fowls common in Rio de Janeiro, and, further, showed that the disease was conveyed by a tick (*Argas*). On reading this paper it occurred to me that perhaps the spirillosis we had found to be so common in Entebbe was nothing else but tick fever. An opportunity of testing this theory soon occurred, when Milne arrived from Hoima, bringing with him blood slides from eight cases of fever, ascribed by the patients to the bites of ticks. These ticks Milne had already had classified by Theobald as *Ornithodorus Savignyi*, Audouin, var. *cæca*, Neumann (?*Argas moubata*, Murray). On hearing of the possible connection between this disease and spirillosis, Milne most generously handed over all his slides to me for examination, and in every one spirochætæ were found. Some two months after the publication of the paper by Milne and myself (4), Dutton and Todd (5) telegraphed from the Congo that they had succeeded in infecting monkeys with spirillosis by the bite of naturally infected ticks (*Ornithodorus*), and the postscript to Dutton's last letter announced that he had infected monkeys by feeding newly hatched ticks on them, thus proving the hereditary transmission from parent tick to offspring through the egg.

The most recent work on the subject of spirillosis is contained in the paper by Borrel and Marchoux (6), who show that at 35° C. the spirochætæ of fowls develop in the body of the tick, which latter suffers from a true spirillosis. At 18 to 20° C. the parasite does not develop, but even after months of starvation, exposure to the higher temperature will cause the increase of the parasite and consequent infectivity of the tick.

Chart I.



Note.—The sign − = No parasites found in blood.

L.M.N. = Large mononuclear ,,
L. = Lymphocytes.
T. = Transitional.

Monkey, No. 34.—Inoculated 1 cc. finger-blood from patient during first relapse, May 17th, 11 a.m. Incubation period, 6 days. Intervals (1) 8 days; (2) 5 days; (3) 7 days; (4) 11 days; (5) 1 day. Differential count May 7th, *i.e.*, before inoculation: P.M.N. 20·5; L.M.N. 19; L. 56; T. 5·5.

The Disease.

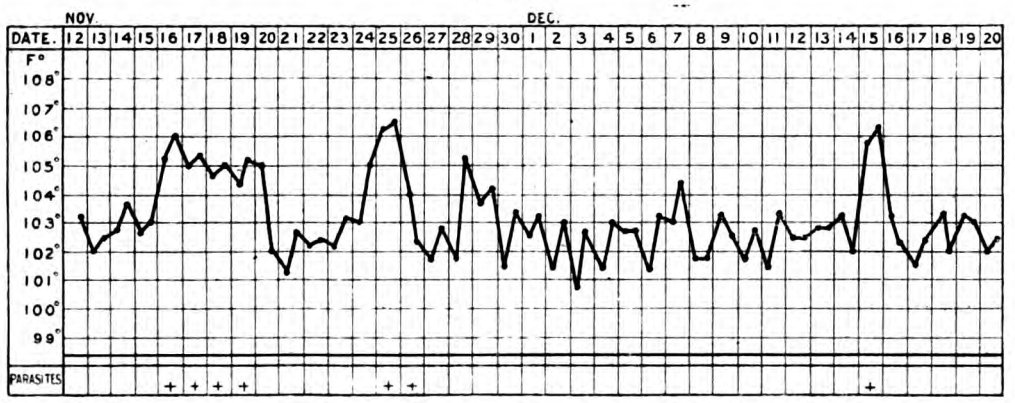
Incubation Period.—The incubation period seems to be from two or three to eight days. The periods of one day given by some natives are probably wrong, and are only the interval since the patient observed

that he was last bitten. As will be seen later, the incubation period in the inoculated disease varies between two and six days.

Onset.—The onset is usually rather abrupt. The patient may complain of not feeling quite well, his temperature is found to be rising, and in a few hours he is prostrate with all the symptoms of the disease.

Symptoms.—In the European the symptoms are fever, headache and vomiting. The temperature rises to 103° to 105°, there is intense headache, sometimes pains in the back or limbs, and most obstinate vomiting. These symptoms last for a varying time; as a rule from twenty-four to forty-eight hours, although they may continue for several days. The temperature then falls suddenly to normal, and all the symptoms are relieved. After an interval of varying length, usually about four or five days, there is a recrudescence of all the symptoms. These relapses may occur four or five times, but have a tendency to become of shorter duration. When at last the relapses cease the patient passes into a fairly rapid convalescence, but during the course of the disease his general health gets very poor and he loses a good deal of weight.

CHART I*a*.



Inoculated November 12th with 1 cc. finger-blood of patient.

In the native, relapses do not always occur, and as a rule there is not more than one relapse. In one of Dr. Hodges' native cases, at the time when a relapse might have been expected, I found the parasite in the blood, although the temperature remained normal and the patient's only complaint was of severe headache. Headache and pains are marked symptoms, and vomiting is more common than in malaria.

Slight hepatic and splenic enlargement may be observed.

Course of the Disease.—In the European there are usually four to six relapses, followed by recovery. In the native there may be no relapse. Death is very rare, and seems only to occur in those whose resistance has been lowered by lack of food, exposure or over-exertion. When it occurs there is a fall of temperature to or below normal, and the patient dies comatose.

Diagnosis.—The diagnosis can only be made with certainty by the discovery of the spirochæte in the blood. The parasites are usually exceedingly sparse in the blood, and it may take many hours' search to find one organism.

The most difficult disease from which to distinguish tick fever is malaria. It is hardly possible to do so by the symptoms alone. If the patient has had malaria recently, his blood may show pigmented leucocytes, and the observer will be apt to content himself with finding these and to put down the case as malarial, but it may be said that a marked rise of temperature in malaria is always accompanied by the presence of parasites in the peripheral blood. There may be very rare exceptions, but personally I have never seen a case of malarial pyrexia where half to one hour's search did not reveal the presence of parasites, unless, of course, the patient had taken large doses of quinine. The reaction to quinine may be a useful point in helping to separate the two diseases. Quinine has absolutely no effect on the temperature or course of the disease in tick fever, but where the reaction is relied on a mistake may easily occur, especially in the initial attack. I have seen a case where the patient was given a large dose of quinine one evening, and next morning the temperature was found to be normal, but it was a case of *post hoc* not *propter hoc*, for in the next attack quinine was again given, but with no effect whatever; but the apparent reaction to quinine in such a case might easily tempt the observer to say that it was malaria, till subsequent events disproved the statement. Reaction to quinine, especially when given by intramuscular injection, would prove the case to be malarial, if this fallacy could be excluded. A European who reacted to quinine and who continued free from fever afterwards while taking quinine would naturally be set down as having suffered from malaria, but a similar course of events in a native would prove nothing. Later in the disease in Europeans, the temperature chart is very characteristic, but it is of some considerable importance to make the diagnosis during the initial attack, as if this be not done, the patient will probably ply himself or be plied with quinine, which is quite useless, and only adds further discomforts to his already miserable state.

Hodges lays stress on the facts that in the native vomiting is more common, and the pains more marked and more complained of in tick fever than in malaria.

Where the blood examination has failed the diagnosis can be made with ease and certainty by injecting a drop or two of the patient's finger blood into a monkey. When the animal sickens the spirochætæ can be found with the greatest ease in its blood. But this method takes a few days.

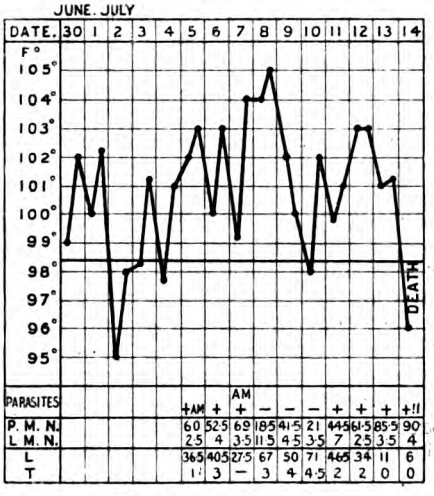
The blood examination will show a relative increase of polymorphonuclear leucocytes. There may also be an increase of large mononuclears, but this latter is of little value in malarial countries.

To sum up, the diagnosis can only be made with certainty by the examination of the blood. The leucocyte count may perhaps give the right clue, and the lack of reaction to quinine may exclude malaria.

Staining.—Leishman's stain is perhaps as convenient as any, and has the advantage over some other stains in that it permits a leucocyte count to be made. Actually the best stain for the parasite is dilute (1 in 3) aniline-gentian-violet for three or five minutes in alcohol or alcohol and ether.

Inoculation.—If a monkey is to be infected the finger-blood may be drawn up into a hypodermic

CHART II.



MONKEY No. 43.—June 30th, inoculated 1 cc. finger-blood from monkey No. 39. Incubation 4½ to 5 days. Duration of first attack, 3 days; interval, 3 days. Duration second attack, 4 days. On fourth morning found prostrate, temperature subnormal, blood swarming with parasites. Death.

Fowl and dog inoculated with 5 cc. heart-blood, but showed no reaction, and no parasites could be found.

Post Mortem.—Lungs, a few very small infarcts. Heart, a few very small infarcts. Spleen rather large, firm, infarcts on surface. Liver rather large, congested, infarcts on surface. Kidneys congested. Lymph glands uniformly enlarged, some of them hæmorrhagic. Brain a little surface congestion, no infarcts.

syringe in which there has been placed a drop or two of a 1 per cent. solution of potassium citrate. The mixrtue is injected subcutaneously.

Treatment.—No drug seems to have any effect either in shortening the disease or relieving the symptoms. All that can be done is to feed the patient in the intervals between the relapse. If a febrile period is prolonged it may be necessary to have recourse to rectal feeding. When convalescence sets in the patient may be given some ordinary tonic, and should be ordered rest and good food.

Prevention.—Prevention is easy for Europeans, but becomes difficult when dealing with natives. The ornithodorus lives by day in the thatch or in cracks of mud floors and walls of old native huts. At night it comes out in search of food, retiring again when it has fed.

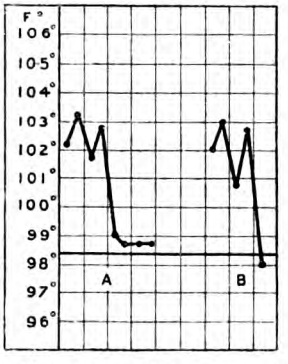
In a country where tick fever is known to exist old camping grounds should be avoided, and native porters and boys should be warned not to use old huts to sleep in. Huts known to be infected should be burned. Europeans will be practically protected by their mosquito nets, provided these be arranged so that they can be tucked in beneath the bed-clothes. Nets with shot-weighted edges to drop to the floor are more likely to be a help to than a protection against the ticks.

It is possible that the reason why natives do not suffer from relapses as do Europeans is connected with their house arrangements. A native living in an infected hut will be constantly subject to reinfection. If, as in other spirilloses, the immunity conferred be only temporary, the native when recovered from one attack will be immune for some time. As the immunity becomes less he will be liable to fresh infection, but it seems likely that the previous attack will have increased his resistance to the disease, and may thus be the cause of the absence of relapses.

THE EXPERIMENTAL DISEASE.

The subcutaneous inoculation of a drop or two of blood from the finger of a patient during fever into a monkey (black-faced or Sykes' Cercopithecus, or Cynocephalus) is sufficient to produce a disease exactly resembling the disease as seen in Europeans. After an incubation period of from two to six days the monkey's temperature rises to 104° to 106°, the animal is found sitting about resting its head

CHART III.



A. Disease in native. Recovery.
B. Disease in native. Death.

on its hands or against the wall of the cage, and evidently feels very ill. In a typical case, after a variable time, usually two to four days, the temperature, which during this time has remained high, falls abruptly to normal, and the animal appears quite well. In five or six days there is again a rise to 104° to 106°, lasting, as a rule, a couple of days, then falling as before. As in the European, there cannot be said to be any regularity either in the duration of the febrile period or in the length of the interval. The fever may persist for nearly a week or last but a day, and the intervals vary between one and eighteen days, but in the later relapses there is a tendency for the

febrile period to be shorter and for the temperature not to rise so high. The animal also is not so evidently ill as during the earlier attacks.

Blood Examination.—If the blood of a monkey be examined when the temperature is first found to be rising it will be found to be swarming with spirochætæ. These are rarely found single, but when so found they are twisted and contorted to a degree not seen in the regular wavy organism seen in man. Usually they are in tangled masses of from four or six to many hundred individuals. Division forms are fairly common. In the fresh blood specimen the parasites are as a rule hard to find in man, but in the monkey they are present in such quantities as to be easily made out. If a single organism can be seen when temporarily arrested in its course its movement resembles nothing so much as that of an archimedean drill. When free it moves much too rapidly for the observer to gather any very clear idea as to its movement. The disturbance of red cells is slight, much less than that caused by a trypanosoma or filaria.

The organisms can easily be found till the crisis, when they disappear even more suddenly than they appeared. In the later relapses the parasites are present in less number than in the earlier attacks, but their behaviour is similar in all respects.

After the first day or two of fever nucleated red cells are found in fair numbers. They persist in the blood till the termination of the illness, and a few may still be found some weeks after the last relapse.

Leucocyte Count.—After inoculation there appears a gradual rise of the polymorphonuclear leucocytes. When the attack sets in there is rather a marked leucocytosis, with a large relative increase of the polymorphonuclear cells at the expense of the lymphocytes. This leucocytosis persists till the crisis, and may become extreme just before the crisis, every microscopic field showing large numbers of leucocytes, especially of the polymorphonuclears. Immediately after the crisis there is a sudden reversion to the original leucocyte count, and this persists till the relapse. A point of interest is that in the later stages of the disease it is sometimes found that the polymorphonuclear increase occurs, although there is no rise of temperature. In two of such cases I have found that long search through a slide has shown the presence of a very small number of spirochætæ. I am inclined to think that in such cases there has really been a relapse, but that it has been so slight that the resistance of the patient being increased by previous attacks, so far as the temperature is concerned, it has proved abortive. Such an attack would probably be comparable to Hodges' case, referred to above, where the parasite appeared in the blood without any rise of temperature, the only sign of relapse being the severe headache.

The mechanism of the crisis in spirillosis has been much discussed, especially by the French working with the parasites of relapsing fever, and of fowls and of geese. Metchnikoff (7) and Cantacuzène (8) are of the opinion that the phagocytes are the agents of the crisis—in relapsing fever the polymorphonuclears, in spirillosis of geese, the macrophages of the spleen. Gabritschewsky (9), on the other hand, ascribes the crisis to the formation of bacteriolysins in the blood serum. Working with the Brazilian disease, Levaditi (10) concludes that in refractory animals the formation of antibodies takes place in the leucopoietic organs, especially in the spleen, bone-marrow, and lymph glands, and the leucocytes should be considered as the principal if not the exclusive source of the antibodies. But in animals suffering from the disease he concludes that "la disparition les spirilles pendant la crise, ne saurait reconnaître l'intervention d'une sensibilisatrice spécifique, considerée comme agent bactériolytique"; and further, "les observations faites sur la septicémie de Marchoux et Salimbeni sont ainsi d'accord avec les constatations de Metchnikoff et de Cantacuzène concernant la fièvre récurrente et la spirillose des oies, pour accorder aux leucocytes une influence de premier ordre dans la guérison spontanée des animaux." The phenomena seen in the Uganda disease would appear to bear out the importance of the part played by the leucocytes. The polymorphonuclear leucocytosis coincides with the appearance of the parasites in the blood, and ends at the crisis which coincides with their disappearance. In both polymorphonuclear and large mononuclear leucocytes clear spaces can be seen, and sometimes, though rarely in the peripheral blood, this space is seen to contain a parasite. In smears of organs after death, especially in smears from the liver and lung, this appearance of parasites, engulphed by the leucocytes, is exceedingly common. After the crisis the vacuoles can still be seen in the large mononuclears, but not in the polymorphonuclears. Where the crisis is due to the formation of bacteriolysins one would expect that the parasites would show loss of motility, signs of degeneration, as shown by change of staining reaction and diminution of numbers. No one of these phenomena is, however, observed.

A marked feature in blood taken during the febrile period is the appearance of the polymorphonuclear leucocytes. Many of these appear to have been so damaged that the mere act of spreading the film converts them into an indefinite mass of nuclear material and granules. In others whose outline is still distinct, there is a marked rearrangement of the nucleus; instead of being rather compact in the centre of the cell, it tends to arrange itself peripherally, leaving a granular space in the middle of the leucocyte. The outline of such cell is much less definite than that of the normal cell.

Death.—Death usually takes place during an early relapse. The temperature of the monkey falls below normal, but the animal does not show the expected improvement. A blood slide taken now will show swarms of spirochætæ, and an enormous leucocytosis. The animal becomes comatose and dies in the course of a few hours.

Post mortem.—The changes found after death are slight.

The lungs show small infarction areas.

The liver is rather large and congested.

The splenic enlargement is slight, and the splenic substance is firm and not at all friable.

The lymph glands are enlarged and some of them are hæmorrhagic.

The brain shows no change.

The heart shows petechiæ in its wall.

Smears of the organs show most parasites in liver,

lung and kidney, and fewest in spleen, brain and lymph glands.

There cannot be said to be anything characteristic in the *post-mortem* appearances in the monkey, any more than there is in man.

It is only recently that I was able to attempt experiments with the ticks. After Dutton and Todd's results in the Congo, I was surprised that the experiments failed, but Borel and Marchoux offer a ready explanation of this in their paper. If the spirochæte does not develop in the tick at 18° to 20° C., it is probable that the tick brought from the moist warmth of Uganda to the cool days and cold nights of Nairobi ceases to be infective, and I expect to have to use the incubator to get any results.

NOTES FROM NORTH NIGERIA.

Liver Abscess, Filaria, Cerebro-spinal Fever, Bilharzia, Spirillar Fever.

By Dr. David Alexander.

[The following is abstracted from a letter dated December 9th, 1905, sent by Dr. Alexander to Dr. Andrew Davidson, Lecturer in Tropical Diseases, University of Edinburgh, to whom we are indebted for forwarding the communication.—Ed., *J.T.M.*]

It may interest you to know, although it has not been published yet, that a friend of mine who has been doing special work in connection with amœbæ, their cultivation and relation to liver abscess, has been able to cultivate them, and has produced liver abscess; this, no doubt, will appear in print soon, unless he discovers some fallacy.

None of the subjects in whom I found *F. perstans* had any illness that could be traced to it, but then consider the number of those who have *F. nocturna* that have no illness either. All the cases I found *F. perstans* in had been in Ashantee: so far I have not got it in any local native yet.

I am surprised that there has been no appearance in print yet of the Principal Medical Officer's report on the cerebro-spinal epidemic. It is endemic and epidemic apparently all over West Nigeria, although I am told that there are no cases up here. At Kano there were a great many cases; deaths include one white man. Kano is 100 miles from here on the one side, and at Sokoto on the other side there were also cases. They also had the epidemic at Yola, so it was present at both extremities of the Protectorate. The natives connect it, somehow, with small-pox, and say that when small-pox is not bad, it is bad. It appears towards the end of the dry season—February, March, and April—and ends with the first rains. None of the attendants that we employed got it, and cases in a town were very irregular in their occurrence; one case here, and the next in a house perhaps 600 to 800 yards away. I never saw a case at home, but it exactly tallies with the description in the text-books. Some of the cases I was inclined to look on as epidemic pneumonia, but probably I was wrong; anyway, we had no differential stains.

Bilharzia I have not come across yet, but that it exists in West Nigeria is certain. Dr. Watson, who made one or two tours in Bornu, tells me he saw it there. (That is Watson of the new *Amphistomum Watsonii.*) Mosquitoes there are many; I have not done much in the way of identification of them.

Spirillar fever I am on the look out for; the ornithodorus is here, and possibly I may have a case. I make a habit of staining a slide from nearly every fever case with carbol-fuchsin, on the off chance of spirilla.

In a note of later date, Dr. Alexander adds:—

I ought not to have said the ornithodorus is here. I described what I wanted to a rather intelligent native, and he said that he knew what I meant, but to-day he brings me in the ordinary bed-bug. However, I may get it yet.

"Indian Med. Gazette," February, 1906.

Prevalence of Yaws in the Chinduin District of Upper Burmah.

Military Assistant Surgeon, P. A. McCarthy recalls that the presence of yaws in this district was first noted by Mr. A. A. Nolan in the *British Medical Journal*, February 2nd, 1895. The disease is known by different names in different townships, some speaking of it as leprosy, and others by descriptive names, such as "crippling disease," "molehill disease," and so on. This variety of names certainly appears to indicate a recent origin, and there is a tradition that it was introduced from Siam *via* the Mergui coast and Chindwin River, and the fact that it is rarely found in inland villages would appear to support the tradition. He considers that the mode of communication is usually by direct inoculation of some breach of surface, and met with it at all ages, from three months to three-score years.

The period of inoculation, though uncertain, he considers to be about three to eight weeks. The author then describes the lesions and course of the disease, which certainly appear to support his opinion as to the identity of the disease with that known as "yaws" in other parts of the world.

He gives some interesting information as to the method of treatment adopted by the native practitioners, or *sayahs*, who employ crude mercury, and occasionally red arsenic. Mr. McCarthy himself used a mixture of hyd. perchlor. and pot. iod. in the secondary stage, and soda lotion, and occasionally sulphate of copper, to the granulomata locally.

In a letter to the editor of the same journal, Lieut.-Col. W. A. Lee, I.M.S., referring to Major Childe's paper on the occurrence of Leishman-Donovan infection in Europeans, states that, unlike Childe, he finds the disease by no means uncommon in Europeans in certain parts of the town of Madras, and draws attention "to the value of carbolic acid, which should be given for a prolonged period, and in gradually increasing doses, to the utmost limits of tolerance." Some of his cases received "as much as 3 drachms daily, with ultimately beneficial results, and without any drawback, such as carboluria, occurring."

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,	5/-;
100	,, ,,	6/-;
200	,, ,,	7/6;
50	Copies beyond four up to eight pages,	8/6;
100	,, ,, ,,	11/-;
200	,, ,, ,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

Journal of Tropical Medicine

MARCH 1, 1906.

THE DEPRECIATION OF THE ATTRACTIONS OF THE INDIAN MEDICAL SERVICE AND ITS REMEDIES.

II.

IN our first article on this subject we drew attention to two causes of dissatisfaction, viz., to the want of encouragement to professional zeal and research, and to the hardships of the superannuation rules, which render it practically impossible for any man who has devoted an adequate time to his student career to reach administrative rank. In the present, we propose to touch on a matter which, though of mainly sentimental interest to the individual members of the Service, is of vast practical importance to the State, as it lies at the very root of the inefficiency of Indian sanitary reform, and in many other directions impairs the efficiency of our medical institutions. We allude to the lack of proper status and influence in the councils of the Indian Empire. Politically speaking, the Surgeon-General with the Government of India is a sort of expert adviser to the Secretary to Government in the Home Department, and when matters of sanitary and medical import have to be dealt with, the latter official may or may not ask medical advice, and, in either case, is perfectly at liberty to ignore it, and probably as often does so as not. Owing to this the position of the Surgeon-General is most unenviable; for the general public, knowing nothing of the gearing of the bureaucratic motor, naturally imputes any blunders that may be committed to him, though they may in reality have been made in defiance of his strongest protests, while official etiquette renders it impossible to utter a word to clear his professional reputation. Nothing can better illustrate the powerlessness of the medical service in the direction of sanitary affairs than the history of the methods of the Indian Government in dealing with plague, of which the following is a short sketch. It may be admitted that the most recent pronouncement of the Simla secretariat on the subject, which we reproduce in another column, is by far the most satisfactory that has been hitherto issued by that august body. One might, in reading it, almost imagine that Simla had taken medical advice on the subject, instead of treating their medical experts as persons most of all likely to take an ignorant and prejudiced view of the question; for hitherto the ways of the Indian Government in the campaign against plague have generally appeared to be based rather on shortsighted notions of expediency than on what might be expected to be the views of their sanitary advisers.

The history of plague prevention in India, however, has been one long series of blunders and mistakes of a sort that could hardly have been committed had the sanitary authorities been trusted to make their own arrangements.

No doubt, at the time of the importation of the disease, the medical profession in India knew practically nothing of plague, but it had had ample experience in dealing with other epidemic diseases, and its intimate personal relations with the native population made it better qualified than perhaps any other branch of the public service to judge what measures would command the loyal co-operation of the people and what would irretrievably offend its prejudices.

As the fact was well known to all epidemiologists that all forms of inland quarantine had hitherto proved powerless to arrest disease of any kind, and as no one understood the ultra-sacredness of the Indian home better than the members of the medical service, it is hardly likely that it can be held responsible for such costly absurdities as sanitary cordons, and train inspections; or for the tactless folly of house-to-house inspection carried out by European soldiers, literally at the point of the bayonet.

The first step in this melancholy tale of misdirection was the ostrich-like one of trying to ignore the presence of the disease in Bombay; and in this way the critical days were wasted, during which stringent measures of isolation and disinfection might possibly have arrested the further spread of the disease. It required no special knowledge of plague to suggest such measures as are required at this stage of an epidemic, as they are self-evident, and have since averted invasion in many parts of the world.

The disease now spread rapidly, and the Government, becoming frightened, attempted to "stamp out" the disease. To this end a Commission, vested with extraordinary powers, was appointed; directed, not as might be expected, by a sanitary officer of proved experience, but by a combatant military officer, who, it may be incidentally remarked, has since proved none too competent, even in his own profession.

Of this Commission the medical officers were simply the agents and subordinates, and its proceedings were of so outrageous a character that, looking back on the time, it is surprising that murder and riot were not even worse aroused than was actually the case; for as if to accentuate its folly the Indian Government appointed, not an officer of the Indian Staff Corps, but one of the British Service who could not by any possibility be acquainted with native prejudices and ideas.

An officer who had grown grey in the sanitary department, who passed through Bombay at this period, remarked at the time to the writer, that he would have lost all respect for the natives of India had they not broken out into riot under the provocation they were receiving.

The mischief wrought by this outburst of mad militarism has been irreparable, as all subsequent measures of the Government, good, bad and indifferent, have been viewed with such suspicion by the native population that it has been impossible to obtain their co-operation, even where they have not resorted to active or passive opposition.

Terrified by the storm it had raised, Government rushed to the opposite extreme, and instead of trusting to the individual tact of its officers to do the little that it had left possible, tied their hands by minute and stringent regulations. To save its face the portentious farce of train inspections was now paraded as the principal line of defence. The medical officers employed on this duty were supposed to examine several hundred people during a halt of fifteen or twenty minutes, and in order to avoid arousing further ebulitions of violence, were, moreover, forbidden to make any sufficient physical examination.

Assuming the patient to be still able to stand, it was in the last degree unlikely that a case could be detected.

Anything more hopelessly futile and harassing than the duties thus thrown on the medical officers employed on the work it would be hard to conceive, and it is probable they were the only people who were more disgusted with the folly of the system than the unfortunate passengers (native and European) who were worried every hundred miles or so by their obviously useless inspections.

Another vagary of this period, born of the desire to appear to be doing something, was the order of a provincial government, that in the chief town of each district every house should be inspected by the Civil Surgeon. The cubic space of each room was to be measured and sanitary recommendations made to each householder. Several of these towns possessed over 25,000 houses, and probably none had less than 3,000 or 4,000, so that the impossibility of a single man, already busy with a multiplicity of duties, carrying out such a task in any reasonable time, even in the smallest places, is sufficiently obvious. As a matter of fact, nothing but rebuilding could convert these oriental houses into sanitary dwellings, and the Government, even if unable to understand this, must have been perfectly aware that nothing whatever would come of the Civil Surgeon's recommendations. What the secretariat evidently did not understand, however, was that the circular, if taken literally by the medical executive, could scarcely fail to cause opposition and rioting. Fortunately, there was hardly an officer in the provincial medical service who had not the tact to practically ignore the order, for every one knew that a broken head and an official reprimand for want of tact was all they were likely to earn by taking seriously such a piece of buffoonery. In one great town, however, it was so obvious, even to the wiseacres at the helm, that the job was more than one man's work, that he was given a couple of youngsters fresh from home to help him in the task. Presumably these energetic recruits must have been so inexperienced as to believe that Government orders should always be taken *au grand sérieux*, for the result was serious opposition, and it was even whispered, disaffection in a native cavalry regiment, though the rumour may be doubted.

Then urgent telegrams went flying over the country, "Cease house-to-house visitation at once." There was probably not a district medical officer in the province who, if asked his opinion, would not have told the authorities that, apart from its futility, such an order was in the last degree impolitic, and it is most unlikely that the very able man who was nominally the administrative medical officer differed from his colleagues on the point. What he may have thought, however, matters nothing, for in any case his powers, whether of action or protest, were practically *nil*.

It would occupy too much space to give a complete history of the later developments of the campaign, beyond saying that of late years the policy has simply been to "let things slide," but enough has been written to show that the course of action has not been what would be expected of men accustomed to deal with epidemic disease in any form, or of officers who in any way understood what sanitary measures are, and are not practicable in dealing with a population whose prejudices are as peculiar as that of India. To thoroughly understand the caste system would probably occupy the lifetime of several German professors, but in the course of fifteen or twenty years' work a sanitary officer attains a fair working knowledge of how to get the maximum possible, under the circumstances, of sanitary effort, and it is the systematic ignoring of this invaluable source of strength that is responsible for the hopeless fiasco that we have attempted to describe.

The old caution of *ne sutor ultra crepidam* is as applicable to attempts on the part of the civil and military executive to deal with sanitary matters as to the cobbler's criticism of the artist. It is not for a moment pretended that the Indian sanitary officials, even if placed in authority, could have succeeded in arresting the advance of the pestilence, but it is certain that no one accustomed to dealing with the native population when attacked by epidemic diseases would have been guilty of the follies that have been described. At least the lacs of rupees

wasted, or hopeless attempts at inland quarantine train inspections, and similar expedients, would have been saved, and we may be sure that coercion would have figured but little in the programme, and if employed at all would have been confined to enforcing the evacuation of infected sites in cases where local circumstances rendered such a measure practicable.

In this way the road would have been smoothed for more effectual measures, when advancing knowledge indicates more promising lines of defence. The remedy lies in giving the Surgeon-General with the Government of India a seat on the Vice-regal Council, and the Inspectors-General of Civil Hospitals one on the Provincial Governments.

It is to be feared, however, that the Indian Government hardly desires to place its sanitary advisers in a position of proper trust and authority, as it is haunted by the fear that this would lead to what they would regard as undue expenditure on sanitary projects.

In reality it would be more likely to result in considerable saving, as no men know better how little can really be done in the present state of civilisation of the indigenous population.

Formerly the Director-General was entitled the "Sanitary Commissioner and Surgeon-General with the Government of India"; but a few months back a great flourish of trumpets was indulged in over the separation of the officers and the appointment of a separate Sanitary Commissioner. In reality, however, the step was a retrograde one, for by a subtle turn of policy the appointment was laid open by "selection" to any grade of the service, and the Government selected a quite junior officer, who, moreover, had had no practical experience whatever in the work of the Sanitary Department, but had been employed for the most of his service in a secretarial post. It is absurd to suppose that so junior an official, however able, could possibly carry sufficient weight to enforce his opinions on a body of veteran "big-wigs" such as constitutes the hierarachy of Simla, and the selection is really an evidence that the latter had no desire to find a medical Kitchener amongst them. A seat on the Council would, however, enable the holder to show that medical officials can be as practical and moderate as other branches of the Service, and would enormously facilitate the progress of such sanitary reform as is practicable under the peculiar conditions of the country and its people.

BODIES IN THE SPUTUM AND FÆCES RESEMBLING THE EGGS OF PARASITES.

Dr. William Hartigan forwarded for inspection peculiar bodies coughed up by a patient in the presence of a medical man practising in the north of Ireland. Of the bodies in question, some to the naked eye resembled ova, and were fairly uniform in size; some resembled freshwater cyclops in their outline and appearance; the remainder, seemingly, consisted of fragments of the above. The bodies in question were submitted for examination to Dr. C. W. Daniels, the Superintendent, and to Dr. C. M. Wenyon, Protozoologist at the London School of Tropical Medicine. The bodies in question were found to be merely mucous casts, modelled, no doubt, in the smaller bronchi of the lung.

This observation is interesting in itself, and in view also of the note by A. Chauffard, in the *Presse Medicale* of January 10th, 1906, referring to the eggs of parasites simulated by pollen in fæcal matter. The ovoid bodies described by Chauffard appeared to be ova, but as they did not resemble the ova of any known parasite they were submitted to a searching investigation, when they were determined to be grains of pollen from a coniferous plant.

J. C.

A Simple Guide to the Preservation of Health in South Africa. By H. Strachan, C.M.G., M.R.C.S., L.R.C.P., P.M.O. Lagos, West Africa. Second Edition.

This is a short pamphlet of no more than seven pages, published locally, it is presumed for gratuitous distribution; but it would be difficult to find elsewhere so much sound advice compressed into so small a space. Though written primarily for the assistance of Europeans residing in West Africa, it is almost needless to say that nine-tenths of its *dicta* are equally applicable to India and other tropical lands.

Though no more than a page and a half is devoted to precautions against malaria, it is astonishing how much has been included in the space; and we are glad to see that Dr. Strachan strongly recommends the adoption of mosquito-proof rooms. He admits that the guaze screens obstruct to some extent the free circulation of air which is so essential to comfort; but points out that "the extra safety to health is worth the extra inconvenience caused by a slightly increased degree of heat." There is, however, no reason why houses should not be so built as to be as comfortable as it is possible to be in such a climate in spite of their being made mosquito-proof.

The remedy lies in increasing the size of the windows and other openings so guarded.

West African houses are, however, usually extremely badly planned in this and almost every other respect of fitness for the climate they have to withstand; but, doubtless, in West Africa, as elsewhere, sanitarians such as Dr. Strachan have little or no opportunity of criticising the plans drawn up by the engineering authorities, and so have to make the best of the latter's bad jobs, after they have become accomplished and costly facts. Provided a room be designed with large openings coming down nearly to the floor, and that the house be so planned that a thorough current of air is possible, there is no reason why breeze enough to blow the papers off the tables should not find entry through wire gauze. We are glad to see, too, that Dr. Strachan recommends the *periodical* and not the *chronic* use of quinine as a prophylactic against malaria, in the form of a full dose (10 grs. quin. sulph., or 6 grs. of hydrochlorate) on two consecutive days weekly. There can be no doubt that the chronic quinine taking, which is so often recommended and practised in West Africa, has a most harmful effect on the nervous system, and indirectly on the general powers of resistence to truly climatic influences; and

that in view of the life-history of the parasite it is quite needless to dose one's self more frequently than is recommended by Dr. Strachan

Much of the pamphlet is naturally taken up with the management of tanks. Foreign as it may be to the popular idea of West Africa as a pathless swamp, the actual facts of the case are that the rainfall is by no means excessive for an equatorial climate, and that some of the most obtrusive discomforts of the country are the outcome of its liability to prolonged periods of drought. The surface wells are bad, and in the absence of regular waterworks, rain-water tanks with all their admitted liability to pollution are the sole available supply.

In some years the practically rainless period may extend to four or five months, even at Lagos, and to much more than this at Accra, so that the sort of stuff that is left at the bottom of the tanks at the end of such a period may be easily imagined, especially before their management was taken in hand by thoughtful sanitary experts of the type of the author of the pamphlet. While, however, the climate is to be considered as a somewhat dry rather than a wet one when compared with the majority of countries in the same latitude, its annual rainfall of 73 inches scarcely qualifies it to pose as a Sahara, and makes it certain that there must be plenty of good water to be got by paying for it. The solution of the difficulty lies with the financial authorities, as the engineers have no doubt excellent plans ready for adoption if only sufficient money be forthcoming. Let us hope that these monetary difficulties will soon be surmounted; for a good and ample water supply is everywhere the first essential of sanitation, and the possibilities of "the Coast" in the matter of health can never be fully realised until Dr. Strachan is able to even further abbreviate his pamphlet, by cutting out his excellent hints as to the management of rain-water tanks, on account of the latter having been replaced by regular water supplies in all centres of population.

THE CULICID FAUNA OF THE ADEN HINTERLAND.

By Lieutenant W. S. Patton, I.M.S.

(*Reprint from the "Journ. Bombay Nat. Hist. Soc.," November, 1905, p. 623.*)

This paper is a valuable contribution to our knowledge of what may be termed the Medical Zoology of a portion of Southern Asia, that up to now has been almost unexplored from this point of view.

Hitherto the whole of Arabia has been a *terra incognita*, and, with small reservations, the same remark applies to Somaliland and the shores of the Persian Gulf.

We must confess, however, that we should not have expected to find the Culicid fauna consisting so largely of new species.

Of the five *Anophilina* described, all are claimed as new, while one of the seven species of Culicines has also not been hitherto described.

The region is, however, a desert one, where the area of distribution of species would naturally tend to be circumscribed, and into which opportunities for the importation of the forms of neighbouring countries must be rare.

The descriptions are full and for the most part excellent, and the figures, though very rough, intelligible. The important detail of the banding of the legs is not, however, described in sufficient detail.

We are not quite clear whether the author adopts the classification of James and Liston, or that of Mr. Theobald, as some of the species have the latter's genera inserted in brackets after "Anopheles," while others have not.

One of the new species, "*Anopheles* (*Myzomyia*) *Jehafi*," is described as having the thorax "covered with brown-curved scales." Now it is a characteristic of Theobald's genus *Myzomyia*, that the thorax, except occasionally on the fore-edge of the mesonotum, should be devoid of true scales, as the chitinous appendages of this region are hair-like, and for practical purposes may be regarded as hairs. The term "curved scale" has a special signification in Mr. Theobald's system of classification, and if it can be correctly applied to those covering the thorax of this species, the genus has been wrongly assigned. The description, in fact, throws it into *Pyretophorus*, where I see the author notes it was placed by Mr. Theobald, who "suggested it might possibly be *A. cinereus*, Theobald." Judging from the plate of the wing I should say it was referable to that species.

It is similarly noted that Mr. Theobald identifies this author's *Anopheles Arabiensis* as his *A. Welcomei* from the Soudan. Now Mr. Theobald is none too loth to make new genera and species, and on such a point as the identification of one of his own species most would prefer to take his *dictum* to that of any other authority, and any attempt to unnecessarily lengthen the already bewildering list of species is much to be deprecated.

Lieutenant Patton did not come across Theobald's *Cellia Pharœnsis* during his researches, though the latter notes that it had been sent him from the Aden hinterland.

There is nothing surprising in this, but, curiously enough, the author evidently considers that Theobald must be referring to some of the specimens sent to the latter by himself, and does not seem to see that they must have been contributed by some other collector.

These, however, are details which need not diminish our congratulations to the author on a good and painstaking piece of work. G. M. G.

Abstract.

TROPICAL AUSTRALIA—IS IT SUITABLE FOR A WORKING WHITE RACE?

By J. S. C. Elkington, M.D., D.P.H.

Tropical Australia comprises rather more than one-third of the entire Commonwealth territory. One-half of Queensland, 523,620 square miles of the Northern Territory, and the north-western divisions of Western Australia, are included, totalling in all some 1,145,000 square miles. The country ranges from the Pacific to the Indian Ocean, includes practically

all ordinary varieties of tropical climate, and is dominated by the monsoonal winds. The greater part of it lies between 600 and 1,500 feet above sea-level, but extensive plateaux exist, covering many hundreds of square miles, at an elevation of over 1,500 feet, and ranging in Arnheim Land to 3,000 feet and over. Sufficient reliable physical cartography has been carried out in Northern Australia to effectively dispose of the old idea that the Northern Territory is a vast mangrove flat, and the remainder an arid waste of sand at or near sea-level. Elevation materially modifies climate, and the breezy tablelands of eastern North Queensland at least afford for many months of the year as "bracing" an atmosphere as can be found anywhere in the world.

Drought is a rare phenomenon in the monsoonal area, and the great northern rivers testify to the abundance and regularity of the annual revivification from this cause. These also afford waterways for considerable distances into the interior, and drain extensive areas of good pastoral country.

After discussing what are the objections to the settlement of a white race in tropical Australia and the problems to be faced, Dr. Elkington concludes as follows:—

"The future of tropical Australia appears to lie in the common-sense of the people, and of their representatives in the Legislature. In its present condition it must continue to form a monument to the lack of enterprise displayed by Australians, and a perpetual temptation to other races and people more appreciative of its varied endowments, and gifted with greater resolution and insight than we appear at present to possess. It is no question to be solved rule-of-thumb fashion by a mere trust in Providence. Tropical Australia should be a prize for the fittest, and if success is desired, every reasonable precaution will require to be taken to insure and maintain that fitness. As one possessing some knowledge of the cost and application of systems of sanitary administration, I am of opinion that this portion, at least, of the necessary administrative organisation will not prove costly, if gradually and sagaciously installed. Concerning its economic value, the facts detailed above will have afforded sufficient indication.

"Before any definite move can be made more will require to be accurately known concerning the topographical and other conditions of the country. From what can be gathered, however, the institution of an enquiry should be amply justified. In this age of land-hunger Australia cannot continue to act as the dog in the manger. Given sufficient industrial attraction, population will soon be forthcoming, and there appears to be no good reason why that population should not be a white one. Should the initial difficulties appear too great, the alternative of a coloured population is always feasible; but I, for one, would regret to think that the national pluck and enterprise upon which we Australians are rather apt to pride ourselves is insufficient to enable difficulties to be faced which have been met and overcome elsewhere under less favourable conditions."

INDIAN GOVERNMENT MANIFESTO ON PLAGUE PREVENTION.

THE following has been issued by the Home Department:

Calcutta, January 18.

"More than five years have now passed since the Governor-General in Council, when reviewing the report of the Indian Plague Commission, examined, in the light of the knowledge then available, various measures which had been proposed or adopted with the object of checking diffusion of the disease, and indicated the considerations of policy which must govern their introduction in India during this period. While the efforts of Government officers have in no way relaxed, and the people themselves have in many places shown a disposition to acquiesce and even co-operate in preventive measures which do not conflict with their social and religious usages, plague has gradually spread to almost every part of India, and subject to certain seasonal fluctuations, tends to recur year after year with undiminished virulence. About a year ago, the Government of India, acting in concert with the Royal Society and Lister Institute, made arrangements for the appointment of a scientific Commission, which is now investigating the causation of plague in Bombay and the Punjab. Pending the completion of these researches, which may extend over a long time, and will in any case be directed mainly to the scientific aspects of the problem, the Governor-General considered it desirable to place on record, in a concise form, the results of practical experience which have been acquired in the last five years of actual plague administration. The Local Governments were accordingly asked for reports based, as far as possible, on the personal experience of their officers, on the conditions affecting the origin and spread of plague, the character of the measures to be adopted against it, the degree of success attained, and the causes upon which success or failure depend. The ample materials thus collected place the Governor-General in a position to indicate those preventive measures which appear, under present conditions, most likely to be successful in the future.

"The most conspicuous change in the opinion of experts in India regarding plague since the issue of the Resolution of July 16th, 1900, is the greatly increased importance now ascribed to the part played by rats in spreading and keeping alive the disease. Rats are exceedingly susceptible to plague, and when once they are infected they usually communicate infection not only to man but also to houses which have undergone a thorough disinfection. It is therefore as essential to the safety of the community to destroy infected rats as to segregate plague-stricken people; in fact, almost all the evidence regarding the causation of plague may be regarded as pointing to the rat as the chief agent in its diffusion. For this reason the importance of destroying rats has been insisted on by the framers of the Paris Convention of 1903, and although European opinion is not unanimous on the point, the Governor-General considers that experience recently acquired in India warrants the belief that the systematic destruction of these animals promises to be one of the most effective measures that can be adopted for preventing the spread of plague.

"Observation has also shown that plague is most severe where the houses of people are crowded together, badly built and imperfectly ventilated, while it usually spares those areas in towns where the streets are wide, houses well built, the alleys and side walks paved, and the drains properly constructed. It follows that municipalities and local bodies should be encouraged and assisted to demolish insanitary quarters, to improve the paving of alleys and sidewalks, to neglect no opportunities of widening the narrow streets, to enforce simple building rules, and perfect their systems of drainage and conservancy. All go-downs where grain is stored should be rendered rat-proof, and should be liable to periodical inspection. In theory the disinfection of both houses and clothing takes a high place among preventive measures, and in cases of pneumonic plague it must be

regarded as imperative; but the great difficulty of carrying out the process thoroughly in a house casts some doubt upon its practical utility, and the Government of India leave it to local authorities to determine the extent to which it should be enforced with reference to prevalent structural conditions. In any case, the efficacy of house disinfection depends entirely upon the methods employed. The fluids used must be really germicidal, such as solutions of corrosive sublimate, cyllin, or izal. They must be intelligently applied under proper supervision, and care must be taken to prevent reinfection of the building by rats. These observations apply in their full force only to towns where the disease has not fully established itself. In villages the disinfection of houses is seldom of much use, while in towns, where plague has become indigenous, the difficulty of completely excluding rats leads to constant reinfection. Of the various measures hitherto adopted with the object of arresting an outbreak of plague none has proved so efficacious as the prompt abandonment of an infected locality for a period that varies with local conditions. In the case of villages, indeed, the evacuation of all houses, accompanied by the systematic destruction of rats, is probably the only means of effectually combating the disease. It is, however, essential that evacuation should be carried out thoroughly. If a portion of the inhabitants remains behind, the disease will continue to spread. In all cases where evacuation is feasible, the people should be encouraged to resort to it, assisted by the grant of blankets and warm clothing, where necessary, and by the provision of huts or materials for building them.

"The evidence which has been collected shows that the inspection of travellers by railway, road and steamship is often successful in averting or delaying the spread of plague, but that the efficacy of this measure depends on the circumstances in which it is applied. It is of most value in protecting limited areas such as hill stations and places so situated that inspection posts command all routes of access. The mere inspection of persons arriving by steamer is, however, of little use unless the rats on board the vessel are destroyed or are prevented from reaching the shore. A segregation camp for the detention of sick is a necessary adjunct to every inspection station, but no one need be detained who is not actually suffering from plague. In all other cases it is sufficient to record travellers' names and addresses and to arrange for their being under surveillance for five days. Experience has shown that mere contact with a case of bubonic plague in a railway carriage involves little danger of infection. The example of prisons proves that quarantine may be relied upon to prevent the spread of plague by human beings, but it can seldom be applied effectually, except by the people themselves, who have sometimes combined to prevent persons from infected places from entering their villages, and have provided accommodation for them outside the inhabited site. In rural areas the adoption of these measures may properly be encouraged, but they do not admit of application to towns. The removal of the sick to hospital, while it is eminently desirable in their own interests, has always been unpopular, and in cases of bubonic plague the necessity for it may be avoided, provided that the surroundings of the patient can be kept clean and free from rats. That the measure is instrumental, however, in delaying the spread of the disease is undeniable, and even though segregation may be relaxed when indigenous cases become widespread, the first few cases imported into a plague-free town should, whenever possible, be segregated without delay. Cases of pneumonic plague, which is directly infectious from man to man, ought always to be segregated. The segregation of persons who have been in contact with a patient suffering from bubonic plague is often impossible in practice. When it can be carried out with the good-will of the people the measure is no doubt useful, but where coercion has to be employed more harm than good is likely to result. In cases of pneumonic plague, however, the segregation of contacts is necessary, as the risk of infection is extreme.

"Inoculation with the prophylactic fluid now manufactured at the Parel Laboratory is of value, not merely for the protection which it affords against plague, but also by reason of its effect in mitigating the violence of an attack. The extent to which it may be adopted depends upon the strength of popular sentiment in its favour or against it, and the Government hope that the people may be encouraged to have recourse to it.

"While the experience of the last five years establishes the utility of the measures enumerated above, it equally teaches that their application must depend upon the circumstances of locality, the character of the people, the stage which the disease has reached, and the agency available for dealing with it. What is necessary in a district free from plague may be useless or vexatious where plague has become indigenous. What is effectual in one part of the country may be inoperative in another. A degree of control which is acceptable to a particular community may be strongly resented by the people who observe a different code of social usage, and in a province with a well-developed system of village officials more can be attempted than in a province where no such organisation exists. Where conditions vary so widely from province to province, as is the case in India, it is manifestly impossible for the Governor-General to lay down a uniform scheme of plague administration. The Local Governments alone are competent to determine what measures are practicable or expedient at particular times and places, and it is upon them that the Government of India rely to make the best use of the opportunities which present themselves for checking the spread of the disease. Finally, the Governor-General would observe that in the last resort all preventive measures depend for their success upon the hearty co-operation of the people themselves, and that every effort should be made to enlist their sympathies and to bring home to them, through their natural leaders and in any other way that may be practicable, that it rests mainly with them to bring about by their own action the cessation of plague in India, as it has long ago disappeared from Europe. When this conviction has been firmly established in the minds of the people, the task of district officers throughout India will be materially lightened, but that can only be obtained by carrying out thoroughly whatever measures it may be decided to introduce, and by impressing upon all officers concerned in plague administration that when a decision has been arrived at there must be no hesitation in giving effect to a policy approved by the Local Government."

Translation.

PRELIMINARY STATEMENT ON THE RESULTS OF A VOYAGE OF INVESTIGATION TO EAST AFRICA.

By R. Koch.

(*Translated from the German by P. Falcke.*)

(*Continued from page* 45.)

(2) Development of Protoplasma[1] (*sic*) Bigeminum.

The *Piroplasma bigeminum*, the active agent of Texas fever, is capable of undergoing a peculiar cycle of development in certain species of tick under particular climatic conditions.

In order to follow this development one should examine the contents of the stomachs of ticks removed from an infected beast which have gorged themselves with blood on several successive days.

The pear-shaped parasite, the chromatin of which has usually already divided into two distinct masses

[1] *Sic* in original. Obviously a misprint in the German article for *Piroplasma bigeminum*. (Smith and Kilborne.)

(fig. 3), leaves the red blood corpuscle and becomes elongated, one of the two chromatin bodies passing to the anterior extremity of the parasite and forming a sharp dark point. The other mass of chromatin remains in about the centre of the parasite, and has a less compact appearance (fig. 4). Ray-like processes appear on it near the point; at first two or three, later on more. At the inferior extremity of the parasite several rays or processes also often develop. The parasite has always an angular, radiating look (figs. 5 and 6). Often it resembles a mace pointed at one end, and exhibiting a granule of chromatin surrounded by stellate rays at the other extremity (figs. 7 and 8).

From the second day there are often found, in addition to the above described forms, others in which two specimens are connected by their posterior extremities, looking like one body with a central piece, and its two extremities furnished with star-like chromatin granules (fig. 9). I consider this form to be referable to some form of copulation. Besides these, globular formations appear, the interior wall of which is strewn at intervals with chromatin, and which in addition have a point of chromatin at the periphery (fig. 10). They convey the impression of having originated from copulating parasites which have cast off the ray-like processes.

The parasites provided with rays have a great tendency to unite into groups of from three to ten or more specimens, amongst which copulating couples may often be found. Moreover, one occasionally comes across longish, oval or pear-shaped bodies, which, when the plasma is stained blue, exhibit a moderately large nucleus of chromatin of granular consistency (fig. 11). These forms appear to me to be a transition to the comparatively large forms, which are likewise pear-shaped, and which I have frequently encountered in the ova of infected ticks (figs. 12 and 13). They are three or four times the size of the piroplasma in the blood of oxen, and it may therefore be assumed that other transition forms must exist. These should be sought for in young ticks. They may, perhaps, be found in the embryos, or immediately after the young are hatched, as it is known that the young tick is capable of conveying infection.

Hitherto I have not succeeded in discovering this transition form.

I was able to demonstrate the conditions of development of *Piroplasma bigeminum* in *Rhipicephalus Australis*, *R. Evertsi*, and in *Hyalomma Ægyptium*, but only in fully developed and gorged ticks and their ova. I never found them in the larvæ, nymphæ or ungorged adult specimens, though I frequently examined them.

(3) The Coast Fever of Oxen.

The parasites of Coast fever differ in so many essentials from the well-known piroplasma of the ox, dog, and horse that they are probably not specifically identical.

They do not exhibit the regular division into two, so characteristic of piroplasma. On the contrary, in Coast fever the parasites are always found to regularly divide into four, arranged in the form of a cross (⁘). This never occurs in the real piroplasma, but has been recorded in the disease discovered by Dschunkowski in Trans-Caucasian Russia, and which he has called tropical piroplasmosis.[1] In horses also there is a disease with parasites in the form of a cross[2] in addition to true piroplasmosis. It is therefore advisable to class those diseases in which cruciform parasites occur in one group.

Another peculiarity of Coast fever is that globular bodies in large numbers are found in the spleen and lymphatic glands; they consist of protoplasm staining blue, and contain a number of chromatin bodies. (The meaning of these forms is not sufficiently clear, and I defer their description till the appearance of my complete work.) Even before the parasites have appeared in the blood these forms are so regularly found in the spleen and glands that I was able advantageously to diagnose the disease in slaughtered animals by their presence.

I also succeeded in discovering the first stages of development of the parasite of Coast fever which are undergone in the tick. In this they are analogous to the *Piroplasma bigeminum*, as they, too, assume angular forms provided with rays; only they are considerably smaller and have fewer corners and rays (fig. 14). It is thus proved that the parasites of Coast fever, notwithstanding the differences alluded to, correspond, as to their developmental history, with the closely related true piroplasma.

It must be mentioned, in addition, that the development of this parasite had hitherto only been observed in adult and engorged specimens of *R. Australis*. This would seem to point to the inference that in Coast fever the infection only takes place by means of the young ticks of this or other species, in which it may be hoped that the further development of the parasites may, ere long, be worked out.

(To be continued.)

Miscellaneous.

THE ESPERANTISTS AND THE *BRITISH MEDICAL JOURNAL*.

The *British Medical Journal* has embroiled itself with the Esperantists, who have taken deeply to heart the Editor's description of their philological plaything as a "pigeon jargon." No class of medical man has better reason for desiring a means of international communication than the student of tropical medicine; but he is as little likely to waste his time on an unscientific attempt to facilitate it as his stay-at-home colleagues, for the very good reasons pointed out by the *B.M.J.*, that languages are evolved and cannot be made.

What the Esperantists appear to overlook is that

[1] By the demonstration of this cross-form I was enabled to confirm the distribution of cattle disease, which is very similar to Coast fever in the countries on the Mediterranean, in East Africa, and New Guinea.

[2] Dr. Kudicke demonstrated the same parasites in the zebra.

there is no need whatever of trying to enhance the curse of Babel by inventing a new tongue, as the acquirement of 2,000 words of any language will enable one to understand and be understood for all ordinary purposes, and hence all that is required is for the nations to decide on the medium of inter-communication.

There is a good deal to be said for the Journal's recommendation of Latin, but this can hardly be carried out in England until we have improved our public schoolmasters and university dons off the face of creation; for their system of teaching Latin by commencing with verse, and ending with a vocabulary of the least useful words and idioms will never give a vernacular knowledge such as is required for the work-a-day purposes of conversation. Added to this, their pronounciation is so barbarous as to be absolutely unintelligible to any foreigner. It may be admitted, too, that the richness and flexibility of the language, and the fact that our terminology is mostly Latin, of a sort, makes its use as a scientific *Lingua Franca* quite practicable, but it is still probable that the Journal underrates the difficulty of adapting it to such purposes. Dead Latin, that is to say, the Latin of Cicero, was evolved to meet the necessities of 100 B.C., and had already been found quite unsuitable to the necessities of the fourth century, A.D., as evidenced by the moans of the "schoolmen" on what they are pleased to call the decadence of the tongue at that period. This, however, is an unscientific view of the case, for the language had not decayed, but evolved; and it is doubtful if any stage of a language that is not in the use of a civilised populace of the present day is really suitable to our needs.

Nothing but international jealousies prevent the most desirable consummation of some one modern language being chosen for the purpose; and however pitiable the reason may be, English, French and German are at once out of court for the very reason that they are the tongues of "great powers." Why, then, should not modern Latin, or, in other words Italian, be chosen?

Ninety-nine per cent. of classical scholars of all nations would acquire a sufficient knowledge of this easy and beautiful language in a tithe of the time that would be required to enable him to adapt his knowledge of dead Latin to colloquial purposes.

So much of the best that has been contributed to tropical medicine has been written in Italian, that a working knowledge of that language is indispensible to all who desire to follow the literature of the subject; but there is no branch of science in which it is not rich, and it is needless to say that its non-scientific literature is second to that of no other nation. Latin is neither dead nor sleeping, but a living reality in its modern form, and in this way what we have learned of it would become of real use to us. Let us hope the question will be considered soon, as Italy is so rapidly advancing to the rank of a great power, that before long the claims its language to serve as an international tongue will have to be ruled "out of the running," and this would be unfortunate for all who have been at the pains to acquire a smattering of what should preferably be spoken of not as dead Latin but as Ancient Italian.

Personal Notes.

Indian Medical Service.

Captains to be Majors.—Cecil Robert Stevens, M.D., F.R.C.S., Leonard Rogers, M.D., F.R.C.S., Gordon Travers Birdwood, M.D., Cecil Charles Stewart Barry, Ernest Alan Robert Newman, M.D., Jay Gould, M.B., Reginald George Turner, James Davidson, M.D., and John Mulvany.

Lieutenant-Colonel W. A. Manson, I.M.S. is confirmed in medical charge of the 11th Lancers.

The services of Captains Hutchinson, Lindesay and Saigol, I.M.S., are placed at the disposal of the Bombay, Bengal, and Burma Governments respectively, the last named for plague duty.

Lieutenant-Colonel W. G. H. Henderson, I.M.S., reverts to military employ.

Captains W. A. Justice and W. Illius, I.M.S., are posted to Madras.

Major C. H. L. Meyer, I.M.S., on relief, to act as Professor of Medicine and Clinical Medicine and Therapeutics, Grant Medical College, *vice* Major L. F. Childe, M.B., I.M.S., proceeding on leave. Captain E. F. G. Tucker, I.M.S., on relief, to act as Professor of Pathology and Morbid Anatomy, and Curator of the Pathological Museum, Grant Medical College. Major C. H. L. Meyer, I.M.S., on relief, to act as First Physician, Jamshedji, Jijibhai Hospital, *vice* Major L. F. Childe, M.B., I.M.S., proceeding on leave. Captain H. Bennett, M.B., C.M., B.Sc., F.R.C.S., I.M.S., on relief, to act as Civil Surgeon, Surat. Captain F. H. G. Hutchinson, M.B., I.M.S., to be Resident Surgeon, St. George's Hospital, Bombay, *vice* Captain C. H. S. Lincoln, I.M.S., continuing to do duty as Deputy Sanitary Commissioner, Southern Registration District. Captain R. M. Carter, I.M.S., has been appointed to act as Civil Surgeon, Jacobabad, from November 1st, in addition to his own duties.

Lieutenant A. F. Hayden, M.B., B.S.Lond., L.R.C.P., M.R.C.S., has taken the Montefiore Bronze Medal and Prize in Military Surgery, and also the Martin Gold Medal in Military Medicine.

Military Assistant Surgeon N. S. Harvey, whose services have been placed at the disposal of this Government, to be Assistant to the Civil Surgeon, Naini Tal, with effect from December 8th, 1905, *vice* Military Assistant Surgeon C. G. Thompson, appointed Civil Surgeon, Garhwal.

India Office: Arrivals Reported in London.—Major J. S. Lumsden, I.M.S. Lieutenant R. F. Steel, I.M.S. Nursing Sister Miss W. M. Aldridge, C.A.M.N.S.I. Lieutenant-Colonel J. Brochi Mills, I.C.V.D. Lieutenant-Colonel J. W. Rodgers, I.M.S. Captain J. W. F. Rait, I.M.S.

Extensions of Leave.—Captain L. Rundall, I.M.S., 6 m., Med. Cert. Lieutenant J. W. H. Babington, I.M.S., 3 m., Med. Cert. Major H. A. Smith, I.M.S., 6 m., Med. Cert. Lieutenant-Colonel L. A. Waddell, C.B., C.I.E., I.M.S., 6 m., Med. Cert. Major F. Raymond, I.C.V.D., 1 m., Furlough.

Permitted to Return to Duty.—Lieutenant-Colonel T. R. Mulroney, I.M.S. Captain R. Bryson, I.M.S. Captain V. St. S. Mores, I.M.S. Major F. Joslen, I.C.V.D.

Colonial Medical Service.

Bridger,—J. F. E. Bridger, M.B. Lond., L.R.C.P., M.R.C.S., D.P.H., Medical Officer of Health, Bridgetown, Barbados.

Clough.—Dr. J. A. Clough, Medical Officer, Lagos, takes over the duties of Resident Medical Officer of the Lagos Hospital.

Frenais.—Dr. A. C. L. La Frenais, L.R.C.P.Edin., has been appointed a Government Medical Officer of British Guiana.

Taylor.—W. I. Taylor, M.D., has left Lagos on leave.

Wise.—K. S. Wise, M.R.C.S., L.R.C.P., has proceeded to British Guiana in the capacity of Government Bacteriologist, a new appointment connected with the Public Hospital, Georgetown. Mr. Wise has resigned his appointment of Demonstrator at the London School of Tropical Medicine which he had held for several sessions.

Domestic.

Births.

Jenney.—At Quetta, on January 24th, 1906, the wife of Major Jenney, I.M.S., of a son.

Maddox.—At Ranchi, on January 24th, 1906, the wife of Major Ralph Henry Maddox, Indian Medical Service, of a daughter.

McKechine.—At Jullundur, on January 25th, 1906, the wife of Captain W. E. McKechine, I.M.S., of a daughter.

Marriages.

Maclagan—Marony.—At the Cathedral, Lahore, on January 27th, 1906, by the Rev. W. B. Handford, Edward Douglas Maclagan, I.C.S., to Edith Marony, niece of Colonel T. E. L. Bate, I.M.S.

Whelan—Longhurst.—At Peshawar, on January 23rd, 1906, by the Rev. J. A. Cunningham, Captain J. F. Whelan, Royal Army Medical Corps, to Geraldine Arden, eldest daughter of the Rev. W. H. R. Longhurst, Vicar of Queenhill, Upton-on-Severn, Worcestershire.

List of Indian Medical Officers on Furlough.

(Under Civil Rules.)

Showing the Name, Province, and Department, and the Period from which the Leave was granted.

Anderson, Captain S., I.M.S., B. Med., to September 25th, 1906.

Anderson, Lieutenant-Colonel A. V., I.M.S., Bo. Med., 20 m. 3 d., September 10th, 1904.

Bennett, Captain V. B., I.M.S., Bo. Med., to June 22nd, 1906.

Browne, Colonel S. H., I.M.S., M.B , C.I.E., B. Med., 7 m. 15 d., September 13th, 1905.

Calvert, Major J. T., I.M.S., B. Med., 21 m., June 6th, 1905.

Clarkson, Major F. C., I.M.S., B.Comm., 17 m., June 16th, 1905.

Close, Major J. K., I.S., U.P. Med., 10 m. 2 d., November 29th, 1905.

Delany, Capt. T. H., I.M.S., B. Med., 17 m. 9 d., April 9th, 1905.

Donovan, Major C., I.M.S., M. Med., 12 m., March 8th, 1906.

Drake-Brockman, Major H. E., I.M.S., B. Med., 12 m., May 5th, 1905.

Drury, Major F. J., I.M.S., B. Med., 9 m., July 4th, 1905.

Duer, Major C., I.M.S., B. Med., 18 m., May 12th, 1905.

Fayrer, Captain F. D. S., I.M.S., M. Medl., 15 m., March 3rd, 1906.

Fullerton, Major T. W. A., I.M.S., U. P. Med., 12 m., February 18th, 1906.

Haffkine, W. M., C.I.E., Bo. Misc., 21 m., July 30th, 1904.

Henderson, Major S. H., I.M.S., U. P. Gaols, 9 m. 14 d., January 18th, 1906.

Hugo, Captain H., I.M.S., D.S.O., B. Med., 9 m., March 6th, 1906.

Irvine, Major T. W., I.M.S., 13½ m., September 29th, 1905.

Kemp, Captain D. C., I.M.S., M. Med., 4 m. 7 d., September 20th, 1905.

Lumsden, Major J. S. S., M.B., F.R.C.S., I.M.S., U.P. Med.

Lumsden, Major P. J., I.M.S., B. Med., 14 m. 13 d., September 10th, 1905.

Maitland, Lieutenant-Colonel I., I.M.S., M. Med., 12 m. March 30th, 1905.

Melville, Major H. B., U.P. Med., 20 m., March 1st, 1906.

Miller, Captain A., I.M.S., M. Med., 15 m., September 11th, 1905.

Morwood, Major J., I.M.S., U.P. Med., 20 m. 7 d., April 7th, 1905.

Mulroney, Lieutenant-Colonel T. R., P. Med., 23 m. 10 d., April 5th, 1904.

Niblock, Captain W. J., I.M.S., M. Med., 12 m., March 1st, 1906.

Orr, Major W. H., I.M.S., U.P. Med., 15 m. 4 d., December 3rd, 1905.

Perry, Captain E. L., I.M.S., P. Med, 9 m., August 15th, 1905.

Prain, Lieutenant-Colonel D., I.M.S., Botanical Department, 19 m., February 1st, 1905.

Rainier, Captain N. R. J., I.M.S., C.P. Med., 7 m. 23 d., November 19th, 1905.

Rait, Captain T. W. F., I.M.S., B. Medl., 19 m., March 21st, 1906.

Rogers., Major F. A., I.M.S., B. Med., 23 m. 2 d., January 14th, 1904.

Rundle, Lieutenant-Colonel C. S., I.M.S., Burma Med., 21 m. 7 d., July 28th, 1905.

Scotland, Major D. W., I.M.S., U.P. Med., 21 m., June 26th, 1905.

Shore, Lieutenant-Colonel R., M.D., I.M.S., B. Med., 15 m., February 1st, 1906.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Bulletin de l'Institute Pasteur," T. iv.

BACILLARY DYSENTERY.

Médecin Major Ch. Dopter points out that dysentery is a symptom of several distinct diseases. There is, for example, a dysentery due to *spirilli*, another due to *Balantidium coli*, and a third to bilharziosis. But the two commonest are the amœboid dysentery of hot countries and the bacillary dysentery, which is found alike in the hot and temperate parts of the world. Though repeatedly noted, it was not till 1898 that Shiga succeeded in distinguishing the bacillus from the *B. typhosus* and *B. coli*. He further demonstrated its specific character by showing that the serum of patients agglutinated its cultures. The bacilli are short, with rounded ends, scarcely motile, not staining by Gram's method, not liquifying gelatin. The colonies, at first punctiform, grow and assume a foliated appearance, with a dark centre and clear periphery. Two years after Kruse found the same organism in cases seen in Westphalia. Since then Shiga's observations have been confirmed by a large number of workers in all parts of the world, and he has clearly demonstrated the specificity of the organism by producing the disease in rabbits, dogs and pigs, and by comparing his cultures and their behaviour with strains obtained from Shiga, Kruse and others. In announcing their investigations, the authorities quoted soon came to the conclusion that, in spite of morphological and cultural resemblances, there are really not one, but several, dysenteric bacilli which differed mainly in their agglutinating power. It was further shown that they differed also in their fermentive properties, the Shiga-Kruse bacillus failing to ferment mannite and maltose, while the Flexner-Manille organism does so. Leutz, however, regards the latter as not pathogenic, but only an associated organism. Park, Collins and Goodwin distinguish three sets of organisms :—

(1) Shiga's bacillus. Does not form indol. Ferments neither mannite, maltose, or saccharose. Inoculated animals yield a serum powerfully agglutinative for this, but only slightly for the other classes.

(2) Bacilli which form indol, ferment the above sugars, and in which the serum of inoculated animals agglutinates cultivations of this type and also those of the third sort.

(3) The Flexner-Manille type, which forms indol, ferments the above sugars,and in which the serum of inoculated animals agglutinates cultivations of this and the second class, and also the *coli* bacilli. Some authors, however, make a more minute classification, but there appears to be a general tendency to regard the Shiga-Kruse bacillus as alone specific, and the Flexner as associated with them. The author then enumerates and describes in detail the organisms that have been described up to date, the general conclusion hitherto arrived at being that cases may be divided into two classes : First, true bacillary dysentery, caused by the Shiga bacillus ; and secondly, a variety of pseudo-dysenteria caused by a variety of pseudo-dysenteric bacilli. He then describes in detail his own observations on these organisms, and discusses the clinical and epidemiological evidence, and concludes that in spite of the arguments brought forward by his predecessors, there is no sufficient reason for subdividing bacillary dysentery.

He admits that in a general way dysenteric bacilli can be arranged in two groups, but it is inexact to assert that the Flexner bacillus can be further subdivided. He, however, regards all forms as really identical, and all equally specific, and on this account considers that such terms as "true dysentery," infantile dysentery, &c., should be abandoned in favour of the one term, bacillary dysentery.

"Journ. of Hyg.," T. jafic. 4, 1905.

SARCOSPORIDIAN FOUND IN THE MUSCLES OF A MONKEY.

Korte, W. E.—These organisms were found in a *Macucus rhesus*, and are the first ever found in any monkey. The parasites are sausage-shaped, surrounded by a capsule which shows a fine striation perpendicular to its surface and filled with spores.

"C. R. Soc. Biol.," T. lix., 1905.

INTESTINAL COCCIDIOSIS OF THE OX IN TUNIS.

Ducloux, E.—He describes a serious malady principally affecting young oxen, and often fatal, charactised by severe diarrhœa, at first liquid and then sero-sanquinolent. The lesions are found in the abomasum and intestine. The epithelial cells of Leiberkühn's glands of the large intestine are found to contain coccidii, which are tetrasporocystic and digoic. Similar cases appear to have been recognised in France and Switzerland.

"Munch. Med. Woch.," T. lii.

PENETRATION OF THE SKIN BY LARVAL ANKYLOSTOMES.

Bruns, H., and Müller, W., obtained positive results in the case of ten dogs on which the larvæ were either placed on the skin or injected beneath it.

Their first two attempts to infect the human subject by placing the larvæ on the skin of the forearm failed, but two others, in which the skin was soaked in warm water for half an hour, succeeded. In the first case eosinophilosis appeared after three weeks and eggs in the stools on the 53rd day; in the second case after 20 and 46 days respectively. The authors consider, however, that infection by the mouth is the commoner and more certain method.

"Lancet," February 17, 1906.

MALTA FEVER IN INDIA.

Captain W. H. C. Forster, who is Deputy Sanitary Commissioner in the Punjab, recalls the fact that Wright, at Netley, demonstrated the specific reaction of Malta fever in patients invalided from India, and these observations were confirmed by Lamb and Birt in India. Doubts were, however, thrown on the accuracy of these observations, and "at the beginning of the present year it was officially held that Malta fever had not been proved to exist as an endemic disease in India." Lamb and Pais have, however, recently removed all doubt on the subject by isolating the *Micrococcus melitensis* from the spleens of Indian cases. These writers *inter alia* described cases occurring among the 14th Sikhs at Ferozapur, and in view of the work of Dr. Zammit and Major W. Horrocks on goats in Malta, Captain Forster decided to repeat their observations on the goats supplying milk to the 14th Sikhs. The result was that 4 out of 38 goats examined gave a positive reaction, and that two of these, which were taken for further observation to the Pasteur Institute, Kasauli, were found to yield milk infected with the specific organism of Malta fever. Any doubts as to the occurrence of the disease in India may therefore be considered to be set at rest.

Notes and News.

PROFESSOR KOCH starts for East Africa early in April.

The chlorine-free culture medium for the *Bacillus lepræ*, by the use of which Captain Rost, I.M.S., in Rangoon, claimed to have succeeded in cultivating the pathogenic organism of leprosy, has been tested by Dr. Frank Tidswell in the laboratory of the Leper Asylum of the Government of New South Wales, but

without success. The stringy, heavy deposits, described by Rost did not appear, and though there were a few of what appeared to be leprosy bacilli in the first culture, none appeared in the second.

It will be noted that this confirms the negative results obtained in a test last year, instituted at the Pasteur Institute, Kasauli. We hope, however, that Captain Rost will not be discouraged from continuing his experiments, which were conducted in a truly scientific spirit, as the practical therapeutic results of the treatment he based on them were, according to independent medical testimony, undoubtedly remarkable, whatever may have been the merits of the theory on which they were based.

Enteric in India.

The (Indian) *Pioneer* devotes a leading article to the the closing of the controversy between Sir Thomas Gallway, P.M.O., in India, and Dr. Leigh Canney, in the columns of the *Times*, as to the etiology of typhoid fever. Dr. Canney advocates the theory that water carriage is practically the only vehicle of infection that need be taken into practical consideration; while Sir Thomas represents what is undoubtedly the opinion of the vast majority of medical observers who have had to deal with typhoid in India and in many other tropical countries. No one, of course, denies the importance of drinking water as a potential vehicle, but it is an undoubted fact that though cantonment water supplies in India have now almost universally been raised above suspicion, their steady improvement has not been followed by any proportionate diminution in typhoid. Water is only one, in fact, of a number of possible vehicles, and in India flies and dust are probably more often implicated than drinking water, and it is in guarding against these sources of infection that further improvement may be looked for.

Plague and Small-pox in Rangoon.

During the last month there were 128 cases of plague, with 126 deaths.

The number of cases of plague for the year ending the 4th ult. in Rangoon, where the epidemic began on February 4th, 1905, is 2,969, with 2,672 deaths. There were in January 425 cases of small-pox in Rangoon, being the largest number yet known.

The Indian plague returns for the week ending January 27th show 3,747 deaths, compared with 4,240 in the week preceding. The principal figures are: United Provinces, 958; Bengal, 896; Bombay Presidency, 707; Punjab, 381; Central Provinces, 484; Burma, 136.

The immunity of Europeans continues to be one of the most noticeable features of the plague epidemic. Last year in the Bombay Presidency, where the disease carried off over a quarter of a million people, only nineteen Europeans in all were attacked, of whom ten died. In the previous year, in the same region, where 316,000 deaths took place, only eight were amongst Europeans.—*Pioneer Mail*, February 9th, 1906.

PURE WATER FOR TRAVELLERS.

In the Tropics and Sub-Tropics where water-borne diseases are so prevalent, and wherever water is suspected of being impure, any apparatus that really purifies water, rendering it sterile and yet leaving it pleasant to the palate and good for the health, must needs be of the highest value and importance. Even the best of filters have their limitations, the objections to them are well known. The "Gem" Pure Water Still, of which an illustration is given, removes all impurities—germs and mineral matter—by the effective process of distillation. The still is in three parts: In the lowest the water is boiled and vapourised, the vapour rises, and striking on the top part, which is filled with cold water, is condensed and trickles into the middle section, whence it is drawn off into a bottle. The still has been approved by high medical authority, and its value has been proved by travellers in Persia, Africa, China, and elsewhere. It is made entirely of metal, there is no rubber or mechanism to get out of order; it is simple, light, portable, effective, and in every way satisfactory. The "Gem" Supplies Co., Ltd., of 121, Newgate Street, London, will send particulars of the still to any of our readers who may enquire. Of course, this still is as useful to residents as to travellers. Indeed, a great many "Gem" stills are constantly in use even in Great Britain, in many parts of which the quality of the ordinary water leaves much to be desired.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the Journal of Tropical Medicine should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communication.

A HÆMOGREGARINE OF MAMMALS AND SOME NOTES ON TRYPANOSOMIASIS IN THE ANGLO-EGYPTIAN SUDAN.

By Andrew Balfour, M.D., B.Sc., M.R.C.P.(Edin.), D.P.H.(Camb.).

Director, Wellcome Research Laboratories, Gordon College, Khartoum.

A Hæmogregarine of Mammals.

H. jaculi—H. balfouri (Laveran).

Being one of the Craggs Prize Essays recently awarded by the London School of Tropical Medicine.

[The first part of this paper was published in the Journal of August 15th, 1905.]

While carrying out work in connection with trypanosomiasis, I have had occasion to make numerous examinations of the blood of the jerboa, or desert rat (*Jaculus jaculus*, or *J. gordoni*, as I believe it has been renamed) (fig. 1).[1]

Fig. 1.

In the first blood examined I was surprised to see that a large proportion of the red blood corpuscles harboured an unpigmented and non-motile parasite. In the stained specimen it was at once apparent that we were dealing with some kind of trophozoite. Twenty-nine jerboas have up to the present been examined, and in all of them, with the exception of two very young animals, this parasite has been found. Specimens were sent to Professor Laveran, who at once declared the parasite to be a hæmogregarine, and has kindly informed me that the discovery is one of much interest. He has further urged me to publish some notes upon its life-history, although my observations are yet far from complete.

The Appearance of the Parasite.—The trophozoite in the fresh blood appears as a pale, hyaline, homogeneous body, slightly curved and with rounded ends (sausage-shaped), lying either apparently free or in the remains of a red blood corpuscle. The latter may be represented only by a bow uniting the two poles of the parasite, just as it is sometimes seen in the case of malarial crescents. The free forms, I believe, owe their condition to a total destruction or absorption of the substance of the erythrocytes which once contained them. As stated, the parasite is non-pigmented and non-motile, and I have found it to be rather resistant, remaining to all appearance unchanged in sterile citrated blood for a period of seventy-two hours, both when kept at room temperature (about 36° C.) and at 22° C. It is to be noted, however, that it altered somewhat in its staining reactions. As a rule, it measures from 5·6 to 7 μ in length, and from 1·4 to 2·8 μ in breadth. The number present has been found to vary considerably. There may be six or seven, or even more, present in each microscopic field (Leitz oc. 4, oil imm. $\frac{1}{12}$), or only a few may be found in the whole blood smear.

Staining the Parasite.—On staining by the Leishman-Romanowsky method, in exactly the same way as for malaria protozoa, the structure of the parasite becomes at once apparent, and the shape, as described above, well defined. A large oval nucleus, constituting, as a rule, about one-third of the organism, is seen to be present, situated generally in the centre of the parasite and stretching right across it, so that there is a deep blue-staining area (the nucleus) in the middle, and a faintly staining blue area with a rounded end on either side. Occasionally, but rarely, and then usually under special conditions, spherical chromatin dots may be found in one or other of these pale polar areas. In stained preparations it is common to find that no vestige of the red blood corpuscle which originally harboured the parasite remains (Plate I., *c*), but careful search will nearly always reveal one or two parasites with portions of the red-staining erythrocyte adhering to them. All that may be present is a thin, red, curved line stretching from pole to pole across the slight concavity of the parasite (Plate I., *a*). Sometimes, especially if the blood be citrated, the relation of the parasite to the blood cell which contains it is beautifully shown. A process of absorption of the cytoplasm of the red cell evidently goes on, and in a severe infection there must be a considerable destruction of erythrocytes. The animal host, however, does not seem to suffer in health. I have kept a jerboa with a considerable infection for three months in the laboratory, and it remained well and lively throughout the whole period. Two others died in captivity, exhibiting violent *ante-mortem* convulsions, and it is worth noting that these rodents do not stand handling well, and must not be supplied with water.

In the peripheral blood it is customary to find all the parasites at or about the same stage of development. True, they differ somewhat in aspect. Thus it is not uncommon to find the nucleus situated at one pole, so that half the parasite stains a deep blue and the other half a very faint blue. Again, one end of the parasite may be pointed, so that the body is club-shaped. This is probably due to alteration during the preparation of the blood smears. In the heart's blood of a jerboa which died naturally I found two distinct forms, a large swollen variety (11·2 μ by 4·2 μ), in which the greatest increase had taken place in the light-staining part of the protoplasm, and a form like those already described (Plate I., *d*). It was very noticeable that the nuclei of the former, often of a triangular shape, stained a deep Romanowsky purple, and frequently did not stretch wholly across the para-

[1] We are informed that *Jaculus Gordoni* has been distinguished from *J. jaculus* on account of differences of coloration, though it is quite possibly merely a local race of the latter.—*Ed. J. T. M.*

site, and in the large pale-staining area three or four spherical chromatin dots were often to be observed.

Professor Laveran has seen this preparation, and points out that such peculiarities in morphology frequently occur. He does not regard these as special sexual forms. At first I was inclined to consider the parasite as being allied to the halteridium of birds. I noted, however, that it was not pigmented, was not curved so much as the halteridium forms, and never exhibited the spore formation at either end as does *Halteridium danilewskyi*.

Endoglobular Hæmogregarine of this Class not Found Previously in the Red Corpuscles of Mammals.—As Professor Laveran kindly pointed out to me, and as, indeed, was soon apparent from a study of the literature, especially Professor Minchin's treatise on the sporozoa, this parasite of jerboa closely resembles the *Hæmogregarinidæ* of cold-blooded vertebrates. This fact is of extreme interest, as I am unaware of any endoglobular parasite of this class having been described in the blood of mammals. Bentley (1) has recently produced a paper on a leucocytozoon of the dog in Assam, but I understand there is some doubt as to his parasite, also described by James (2), which, moreover, affects the leucocytes. The classification of this order of parasites given by Professor Minchin is as follows :—

"Order *Hæmosporidia* (Danilewsky).

"Sub-order I. *Hæmosporea*.

"Genus i. *Lankesterella* (Labbé, 1899) for *Drepanidium* (Lankester). The hæmogregarine is not more than three-quarters the length of the blood corpuscle it inhabits.

"Genus ii. *Karyolysus* (Labbé, 1894). The hæmogregarine does not exceed the corpuscle in length.

"Genus iii. *Hæmogregarine* (Danilewsky, 1897), (syn. Danilewsky-Labbé, 1895).

"The body of the parasite when adult exceeds the corpuscle in length, and is bent on itself within it in a characteristic manner like the letter V."

Now the parasite of the jerboa in question does slightly exceed the corpuscle in length, but is only slightly curved. It looks as a rule as if it had outgrown its corpuscle, and sometimes the remains of what has evidently been a distended and distorted corpuscle can be seen lying around it. The large, swollen, and bloated forms are much larger than the corpuscles which originally contained them, and are found lying free. On several occasions, and especially in fresh preparations from the bone-marrow, I have noted forms slightly turned up at one end and looking like an incomplete letter V. I have not been able to demonstrate this appearance in stained specimens.

Laveran's classification, in which the genus *Hæmogregarine* is made to include *Drepanidium* and *Karyolysus*, is more simple, but whichever be adopted, it would seem that this parasite is undoubtedly a hæmogregarine, and I propose to give it the provisional name of *H. jaculi*,[1] though it is quite possible it may be found in other mammals. Indeed, I have recently discovered what seems to be the same parasite in the mononuclear leucocyte of the Norway rat (*Mus decumanus*) in Khartoum (Plate I., *f.*). It is probable that it exists as a leucocytozoon in the rodents, but further observations are required. I have once found free forms in smears from the splenic pulp of a Norway rat.

Reverting to the parasite of the jerboa, a study of its life-history has further indicated its relation to the *Hæmogregarinidæ*, for I have succeeded in finding two further stages, *i.e.* :—

(1) The free, motile vermicule form.

(2) The stage of schizonts in the form of cytocysts.

In one instance only have I found the free trophozoite. I discovered two such forms in the peripheral blood of a jerboa, which showed the endoglobular trophozoite in fair numbers and which had some injections of the serum of a water-buck in connection with the trypanosome work.

A Free Motile Form of the Parasite.—This free form is in length about three times the diameter of a red blood corpuscle, is pointed at both ends, and moves very slowly through the blood, progressing by a series of contractions of its cytoplasm, the so-called "euglenoid" movements. As a result constrictions appear in the body of the parasite, as many as three having been seen present at one time. These, so to speak, run along the body of the parasite, which thereafter assumes its usual cylindrical shape and glides steadily across the field, always proceeding in one direction and with the same end in front. It pauses for greater or longer periods, undergoing various alterations in shape.

If it encounters a clump of red blood corpuscles it disappears among them, producing only a slight agitation amongst the erythrocytes, which it pushes out of its way. Granules are visible in the posterior part of the body. No flagellum has been seen nor anything to suggest the extrusion of a gelatinous thread, as occurs in the case of some of the gregarines. I have been fortunate enough to secure a stained preparation of this free trophozoite, the appearance of which further demonstrates its resemblance to a hæmogregarine (Plate I., *b.*).

Anteriorly there is a somewhat sharp-pointed area staining a light blue and in which close to the nucleus a chromatin dot is visible. Following this clear area comes a very lengthy, oblong, deeply stained nucleus. At one point it showed a constriction similar, no doubt, to those seen in the fresh preparation. It had been killed, fixed, and stained in the act of progression.

Behind the nucleus is a lengthy, light-staining area, terminating in a pointed extremity. This area stains a light blue with the Leishman stain and exhibits a cluster of chromatin dots, arranged in a somewhat rosette form immediately behind the nucleus. I noted a single central dot with six others arranged in a circle around it. A few similar dots, irregularly arranged, are also visible close to the posterior extremity.

Measurements :—

Total length	15·5 μ
Length of the nucleus	7 μ
Length of anterior light area ...	2·8 μ
Length of posterior light area ...	5·7 μ
Greatest breadth	2·8 μ

The nucleus, it may be said, stretches completely across the body, entirely separating the anterior from the posterior moiety. The broadest part of the

[1] Professor Laveran has recently written me to say that he has given the name of *H. balfouri* to this parasite.

parasite is towards the posterior end of the nucleus. In most cases a third stage can be readily demonstrated. This is chiefly seen in the liver and kidney, organs where the circulation is slow, and will probably be found also in the bone-marrow and brain. Indeed, some smears of the bone-marrow have shown what were probably empty cytocysts. In thick smears from the liver and kidney well-defined cysts are found, the walls of which are apparently formed by the remains of cells of these organs which have been destroyed by the parasitic growth (Plate II.).

These cysts vary much in size. The largest I have noted occurred in a liver smear and measured 39·6 μ by 33·6 μ. A common dimension appears to be about 22·4 μ by 16·8 μ, but many smaller cysts occur.

It is usual to find some of these cytocysts empty, or at the most containing a little residue protoplasm, but a certain proportion are found to contain merozoites (Plate II.), readily recognisable by their shape and nuclei, and somewhat resembling the trophozoite stage in the blood. The nuclei, however, are comparatively small, and in many cases the merozoite appears to be longer and more pointed at the ends than the endoglobular trophozoite.

Schizont Forms.—Early schizont forms also occur, in which the protoplasm contained within the cyst wall has not been differentiated and stains more or less uniformly. Sometimes darker-staining portions indicate the future nuclei of the merozoites. When complete division has taken place some residual protoplasm remains behind, and the whole condition is very like that which has been described by Labbé (3) in the case of *Karyolysus lacertarum*. Sections of the liver stained by the Giemsa method show all stages of the schizonts. Mitosis of the nuclei and the formation of daughter nuclei are well seen.

Appearances are very like those presented during the schizogony of some of the Coccidia, notably *Adelea ovata* are exhibited, and the whole condition from the invasion of the liver cell to the bursting of the cyst and the freeing of its contents can be traced. The merozoites in a ripe cyst can be seen to be arranged side by side nearly all round the periphery of the central undifferentiated mass of protoplasm which remains as the residuum.

By what channel the hepatic cell is invaded has not as yet been determined, but it is probably through the capillaries.

The interesting appearances presented by these liver sections, which were kindly prepared for me by Mr. Richard Muir, of the Pathological Department, University of Edinburgh, and required detailed study, are further confirmation, if any were required, that this parasite of jerboas is a hæmogregrine.

Laveran (4) has pointed out that the schizont stage of these parasites in reptiles is passed in the liver, and Labbé has given much attention to this subject. I have not yet been able to decide whether dimorphism occurs, and if micro- and macro-merozoites can be distinguished, but it is probable that such will be found to be the case.

Before seeing the liver sections I was under the impression that the non-sexual cycle was as follows: The trophozoite is set free from the erythrocyte as the travelling vermicule, which eventually penetrates a cell of the liver or kidney, and gives rise to schizonts in the form of cytocysts. In these the merozoites are formed which, after certain changes, eventually escape into the blood stream, invade red blood corpuscles, and so restart the cycle of schizogony.

So far, however, one has not been able to see anything like the travelling vermicule in the liver sections. The form invading the hepatic cells looks like the trophozoite of the peripheral blood, or, at the most, one of the swollen forms already mentioned. Is it, then, possible that the travelling vermicule plays no part in this cycle? This is possibly so; or, again, as Labbé asserts, for Lankasterella and Karyolysus an isogamic conjugation may take place between two of these free forms, and it may be the zygote so formed which can be seen penetrating the liver cells. Many, however, disbelieve Labbé's conclusions, which have not been confirmed by the observations of Hintze (5) on Lankasterella, so possibly the free trophozoite directly invades the liver cell and becomes the schizont, while the free vermicule is intended to play a part in an extracorporeal sexual cycle. This leads us to consider the habits of the jerboa and the parasites which it harbours.

The rodent is a nocturnal animal, living in holes in the desert, remaining invisible throughout the day, but found hopping about in the evening and on moonlight nights. It exists far away from any water, which it does not seem to require, and its food probably consists of the minute seeds of the small plants which contrive to exist in sandy wastes. The animal is easily caught in traps baited with millet.

Both fleas and mites are found on the jerboa. The species of *Siphanoptera* present has not been determined, but I have dissected and examined the internal organs of engorged fleas taken from infected animals. My observations have been limited, but, so far, though I have found unaltered parasites in the blood from the stomach of a flea, nothing has been seen which suggests that a stage is passed in that insect. Further dissections are required. Some blood containing endoglobular trophozoites was placed in the acid citrate solution devised by Rogers (6) to stimulate the conditions present in an insect's stomach. Though kept in this medium for over forty-eight hours at room temperature, no change took place in the parasites, save that their cytoplasm became more granular.

I have not be able to examine the mites, which are extremely minute and not very often present. As the jerboa is nocturnal, I thought it well to chloroform one during the night, and at once examine its blood and organs. I failed to find the vermicule form or anything but the free and endoglobular trophozoites.

It should be said that to the naked eye there is no morbid appearance presented by any of the viscera. The spleen seems never to be enlarged, and, as far as can be told, the liver does not appear abnormal.

Further, it may be stated that numerous free forms (trophozoites or merozoites) are usually present in smears made from the liver, kidney and bone-marrow, and to a less extent in those from the spleen.

Professor Laveran writes me to say that he has now found the same parasite in jerboas from Tunis, so that no doubt much information will soon be forth-

coming regarding this interesting parasite of mammals. It will be of special interest to determine if it really exists as a leucocytozoon in *Mus decumanus*, or whether in the case cited the mononuclear leucocytes were merely taking on a phagocytic action, or whether the parasite found in the Norway rat is another distinct variety.

In concluding this paper, I would record my sincere thanks to Professor Laveran for his kind interest and advice; my indebtedness to Dr. Beam, chemist to the laboratories, for the photomicrographs; to Mr. Muir for the drawing of the vermicule; and to my laboratory assistant, Mr. Friedrichs, for his useful aid in the work.

SOME NOTES ON TRYPANOSOMIASIS IN THE ANGLO-EGYPTIAN SUDAN.

In the *British Medical Journal* of November 26th, 1904, I published a preliminary note on the above subject. This article referred to the fact that I had found trypanosomes in the blood of a donkey from the Bahr-el-Ghazal, that Head (1) had discovered similar parasites in mules from the same region, and that in smears from the blood of Shilluk cattle which he had submitted to me for examination I had found these flagellates. Since that paper appeared a considerable amount of information has been obtained, and a good deal of research work has been carried out in the laboratories upon what is a very important subject in a country like the Sudan. The following are the chief points to which I wish to direct attention:—

(1) The prevalence and distribution of trypanosomiasis in the Sudan.

(2) The presence in cattle of a small trypanosome which Laveran has declared to be a new species, and which he has named *T. nanum*.

(3) The question as to whether equines, or at least mules, are liable to a double infection by two different species of trypanosomes, or are the hosts of a *T. dimorphum* resembling that which affects horses in Senegambia.

(4) The great frequency of hæmorrhagic ulcerative lesions of the stomach in trypanosomiasis and their significance, also the comparative frequency of intestinal ulceration.

(5) The occasional presence of spirilla in these gastric lesions, both in the blood clot adherent to the ulcers and in the ulcerated surfaces.

(6) The action of chrysoidin as a therapeutic agent in trypanosomiasis.

(7) The therapeutic action in trypanosomiasis of the blood serum of wild animals (big game), whose habitat is in trypanosome-infected areas, a line of research suggested by Dr. Sheffield Neave (*vide infra*).

(1) *As regards Prevalence and Distribution.*—There can be little doubt that in the Southern Sudan, that is to say, in the region south of the tenth parallel of latitude, trypanosomiasis exists to a very considerable extent. An illness known to be due to the bites of tsetse-flies, and affecting donkeys, horses, mules, and possibly camels, has been recognised in the Bahr-el-Ghazal province since that distant region was visited after the reconquering of the Sudan. Expeditions have experienced considerable losses in transport animals from this cause. Again, and more recently, sick and emaciated animals have been coming from the Upper Sobat district, and especially from the neighbourhood of Itang, a station on the Baro River, in Abyssinian territory.

Old records also speak of animals dying from fly-bite on the upper reaches of the Blue Nile, but accounts are so vague, both as regards the nature of the illness and that of the fly said to cause it, that no definite conclusion can be reached regarding the prevalence of trypanosomiasis in that region. No cases have been sent me from the Blue Nile provinces, and I have not received s amples of tsetse-flies from these parts, nor seen them between Roseires and Wad Medani, where the river is more or less bordered by bush and forest. In the Northern Sudan, the region of sandy wastes, as pointed out in the preliminary note, trypanosomiasis has not been found to exist; but no great number of examinations have been made, and investigations upon frogs, lizards, and a large number of birds have yet to be conducted. Dr. Sheffield Neave, Travelling Pathologist to the Laboratories, has been working down Nile from Gondokoro, and has found trypanosomes in at least three species of Nile fish, in a lizard, in kites, and in vultures. These finds in birds are especially interesting in the light of Novy's and M'Neal's recent researches. (2)

For the purpose of gathering information and material regarding the trypanosomiasis of Shilluk cattle, I accompanied Colonel Griffith, the Principal Veterinary Officer, to Taufikia, near the mouth of the Sobat River, and 522 miles south of Khartoum. The journey was undertaken in January, 1905, and at Melut, fifty miles north of Kodok (late Fashoda), a herd of Shilluk cattle was inspected. Three sick animals were picked out and examined. In the blood of one of these I found a trypanosome identical with the parasite found in Shilluk cattle at Khartoum which had come from the Kodok region.[1] Nothing was found in the blood of the other two animals, but it is probable they were suffering from the disease, as they presented the characteristic symptoms, *i.e.*, extreme anæmia of the mucous membranes, weakness, emaciation, and some running from the nose. At Melut we received vague information as to the presence of a fly-belt a considerable distance inland, and were told that the cattle became infected after the rainy season, *i.e.*, in August. On these cattle, as in those at Khartoum, large numbers of the tick called *Amblyomma variegatum* were found, as well as flies of the genus *Hippobosca*. It may be said at once that examination of these insects has always proved negative, but, as will be shown, the trypanosomes are never very numerous in the blood of cattle.

[1] The recent discovery of *G. morsitans* in Southern Kordofan probably explains the prevalence of tsetse diseases in this district.

A herd which had just been imported from the north showed no signs of disease.

At Kodok a small herd was seen, and one sick cow, which eight months previously had come from Melut, was examined. It was distinctly thin and anæmic, but no parasites were found in its blood.

At Taufikia six separate herds of cattle were inspected, the bloods of twelve sick beasts were examined, and trypanosomes were found in one animal only—a cow from Abyssinia—which had recently aborted and was in a dying condition.

This trypanosome proved to be *T. nanum*. Three sick mules, coming also from near Itang, were found to harbour trypanosomes. These were not the same species of parasite as those found in cattle, but appear to be identical with those discovered by Head in mules from the Bahr-el-Ghazal. A dog was inoculated from one of these mules and brought to Khartoum, where it developed trypanosomiasis. It was from this strain, carried on by successive passages through animals, that I have been able to study the parasites of the disease in mules. The cow from Melut was also brought to Khartoum, and will be again mentioned in due course. At Taufikia a monkey (*Cercopithecus sabaeus*), a bat, and a black and white crow were examined, with negative results.

Out of three sparrow-like birds examined, two showed halteridia in the blood.

It is difficult to base any conclusions on such limited observations. The trypanosomiasis of cattle is a chronic disease to all appearance, and it will be some time before its prevalence is correctly gauged. In equines the malady appears to be common in the Bahr-el-Ghazal, where *G. morsitans* is found, and probably exists to a considerable extent on the Upper Sobat. On the mules at Taufikia large numbers of a species of Stomoxys were found, biting fiercely, specially in the evenings. No opportunity of properly examining these flies was afforded. In one, which was dissected, no trypanosomes were found, but several hours had elapsed before its stomach contents were examined. One may here refer to human trypanosomiasis, which so far has not been encountered within the confines of the Sudan, though, as previously noticed, Dr. Neave (3) found Leishman-Donovan bodies in the spleen of a boy coming from Meshra, in the Bahr-el-Ghazal. At Taufikia I found that a Sudanese battalion was being recruited to some extent from Uganda, and discovered that twelve men had come from Kampala, close to Entebbe, a centre of the disease. Some of these men exhibited enlarged cervical glands. They were tested by blood examinations, gland puncture, and, in one specially suspicious case, inoculation into a monkey (Cercopithecus), but with wholly negative results. Later they were sent for observation to Khartoum, and were re-examined, but no trypanosomes were found. The presence of these men at Taufikia, however, served to draw attention to what was undoubtedly a source of danger. Recruiting from Uganda has been abolished.

Lieutenant Gray (4) has shown that the country immediately south of Gondokoro is not of the kind likely to harbour *G. palpalis*, and neither Dr. Neave nor I saw anything of tsetse-flies on the Upper White Nile. As *G. morsitans* haunts the forest districts of the Bahr-el-Ghazal, there is nothing to prevent *G. palpalis* being likewise an inhabitant, and Dr. Neave's trip through that region may serve to settle this important question.[1]

(2) *The Disease in Cattle.*—Cattle trypanosomiasis has been studied in Khartoum, Melut, and Taufikia. The disease appears to be of a chronic nature, the principal symptoms being extreme anæmia, especially visible in the blanched, glistening, conjunctival surface, weakness, emaciation, running from the nose, and occasional dripping of urine. The last condition is probably dependent on muscular weakness. Plate III., fig. 1, gives a good idea of an animal suffering from the disease. Notice the dull, listless, half-closed and sleepy eye, the prominent ribs and hip-bones, and, what is rather constant, the atrophic line in the shoulder hump. In the later stages the head is held low, and towards the end there is complete collapse, the animal lying down and refusing to rise, the skin cold, the coat roughened, urine and fæces passed involuntarily, and the respirations noisy and rapid. At this stage the animal may take food, and, indeed, failure of appetite does not at any time seem to be a symptom. Careful examination failed to detect enlarged glands towards the root of the neck, but one is apt to be deceived by feeling the subcutaneous gelatinous exudation which is found to exist *post mortem*. The first ox from which specimens were obtained died some fifteen miles from Khartoum. Smears of the peripheral blood, liver and spleen were submitted to me by Captain Head. In all of these I found the small trypanosome since named *T. nanum* by Professor Laveran. Captain Head also brought in some of the cerebro-spinal fluid, which was centrifuged, and in the sediment streptococci, possibly due to contamination, and altered and amœboid forms of the parasite, were found. The latter resembled those described by Plimmer and Bradford (5) in bone-marrow in cases of nagana, and by Castellani (6) as occurring in the cerebro-spinal fluid in sleeping sickness. They were few in number and stained feebly. A somewhat pear-shaped, flagellated form was the most striking.

The second ox also died at a distance. In smears made from its blood trypanosomes were fairly numerous. The stomach, which has been placed in spirit, was the only organ brought to the laboratories. Attached to it was a small piece of omentum. On opening the stomach, a very curious condition of pigmented ulceration was disclosed, affecting the mucous membrane (Plate III., fig. 2). Scattered about were dark areas with thickened edges raised above the surrounding mucous membrane. The surfaces of these areas were flat and slightly depressed, and consisted of what was afterwards found to be altered blood clot. No smears were made from these areas, but sections were cut and examined. Beyond a severe bacillary invasion and the appearance of considerable

[1] Dr. Neave did not find *G. palpalis*, but it has been reported as existing at Wandi, in the Lado Enclave, and at Mvolo, in the Bahr-el-Ghazal. The report requires confirmation. I have recently heard that Major Bray, of the Egyptian Medical Service, has sent to Khartoum a specimen of a fly taken near Mvolo. It is believed to be *G. palpalis* by Captain Ensor, who examined it, and is my informant.

erosion and destruction of the mucous membrane, nothing was found.

The following are my notes on the condition :—

Examination of Abomasum or Fourth Stomach—Cardiac End.—Nothing noticeable externally. In a small piece of attached omentum there are two enlarged glands about the size of peas, rounded, elastic to the touch, purple in colour externally, and deep purple on section. The mucous membrane is of a uniform dark slate colour, no ecchymoses are present, but there are some dark patches, possibly due to *post-mortem* changes. Studded over the surface of the mucous membrane are spots of intensely black pigment (Plate III., fig. 2). Each of these, in most instances, seems to surround a tiny punched-out hole, and the pigmentation is most marked in the central depression. A few black granules can, as a rule, be squeezed out from the central pits. These granules were found to consist of altered blood. Where the patches are more advanced they present the appearance of ulcerations. Most of these are more or less circular and depressed, but some are in the form of ulcerated streaks, and all are intensely black. In addition there are a few patches of superficial pigmentation in which there is no ulcerative process.

Central Portion.—The condition is very similar, but the patches are larger, some of the ulcerated "streaks" being ¾ inch in length. In one or two places the ulcerations appear to have healed, leaving depressed and whitish scars surrounded by areas of slight pigmentation.

Pyloric End. — Nothing noted externally. The mucous membrane shows a general pigmentation of the surface in the form of little circular shallow pits with pigmented walls, the pigmentation being very slight. In addition, pigmented ulcers similar to those previously described are present in considerable numbers, and in some instances a regular plug of the black material fills up the ulcer, and rises above the surface of the mucous membrane. There are also present the superficial pigmentations already mentioned, some of which are associated with slight erosion. Where ulcers are marked their edges are thickened. The ulcerative process and the pigmentation are confined to the mucous layer. In no instance does perforation seem to have occurred. Size of largest ulcer, ¾ inch by ¼ inch.

At the time I did not think that these ulcerations, which rather recalled the lesions produced by the swallowing of a corrosive poison, were in any way connected with the trypanosomiasis. Since then I have had reason to alter that opinion, as will be seen when we consider the experimental work with the trypanosomes of mules. Lieutenant Gray, whom I met on his way to England from Uganda, informed me that he had recently found a similar condition of ulceration in the stomachs of natives dead of sleeping sickness.

The third ox is that shown (Plate III., fig. 1). The blood was taken at Khartoum on October 30th, and as many as two trypanosomes were found in some fields. The animal was kept and well fed. On November 4th fresh and stained blood films were examined, but no parasites could be demonstrated. Thereafter, though the blood was centrifuged and examined, and though the animal was subjected to four days' partial starvation, trypanosomes were not again found. Eventually, as the owner wished to slaughter the ox, it was exchanged for Ox No. 4, which was examined on November 23rd, when a considerable number of trypanosomes were found, as many as six per cover-glass preparation being present. This ox continued to show the parasites in its blood, and gradually became thinner and weaker.

On December 3rd it was found to be very weak, with marked anæmia and dribbling urine. The urine and fæces were examined for blood, but none was present. The fæces were slightly tarry in consistence, and this and their colour suggested the examination.

On December 4th the ox was found to be *in extremis*. Trypanosomes were slightly more numerous in the blood, and as it was feared the animal might die during the night it was slaughtered and an autopsy performed immediately.

The principal points noted were :—

(*a*) The extensive subcutaneous, gelatinous, and pale yellow exudation. Nearly every part of the subcutaneous connective tissue was in an œdematous, watery condition, which was most marked where the skin was loose, *i.e.*, in the dewlap, behind the shoulders and in front of the haunch.

(*b*) The presence of enlarged, purple, hæmorrhagic glands about the root of the neck.

(*c*) The great and general enlargement of the mesenteric glands, which were also, though to a less extent, hæmorrhagic in nature.

(*d*) The presence of a certain amount of chronic meningitis affecting the pia arachnoid, the pia being somewhat adherent to the surface of the convolutions. There was little thickening of the membranes, and no appearance of encephalitis; indeed, the brain appeared markedly anæmic. The stomach, which was distended with food, presented no ulcerative condition, but contained "bots" of a different kind to any I have seen in the Sudan. The intestinal tract was normal. There was nothing special to note with regard to the spleen and liver, which were neither congested nor enlarged. The heart's blood showed trypanosomes. Fluid from the lateral ventricles of the brain and from the cerebro-spinal fluid showed nothing in the way of trypanosome infection. Bile taken with aseptic precautions from the gall-bladder contained a short stout bacillus in considerable numbers, but no flagellated parasites.

The cow at Melut was picked out by the natives as being ill. The blood was collected in tubes containing citrate of soda solution. Such blood showed trypanosomes, though these were only found after some searching.

The Abyssinian cow which aborted at Taufikia, and was in a dying condition, also had trypanosomes in its blood, but they were not at all numerous. Time did not admit of a *post-mortem* examination in this case.

The trypanosome concerned is a small one. It is not very active in fresh films, and I have never seen one traverse the whole field of the microscope. The motion is undulating, combined with a vigorous slashing to and fro of the anterior part of the body, which tapers to a very tiny flagellum. Rippling and what

may be termed spreading movements have also been observed. The parasite advances usually with the narrow end in front, but this motion is often reversed, and I have seen one move a considerable distance, pushing aside the erythrocytes with its blunt posterior end. A fact which is very noticeable is that the trypanosome tends to adhere to the red blood corpuscles. Even in a thin field this is seen, the parasite seeming to take a delight in butting and boring at the erythrocytes. Frequently it gets beneath them and is lost to view, the agitation it produces being the only clue to its presence. Having studied this trypanosome, both in the living and stained condition, and having conducted a few inoculation experiments on laboratory animals (*vide infra*), I became convinced that this was either a new and undescribed trypanosome, or was identical with the parasite of cattle found by Bruce, Nabarro, and Gray, on the shores of the Victoria Nyanza in Uganda. Stained specimens were sent to the Liverpool School of Tropical Medicine, but I learn that unfortunately the stain had faded and could not be repeated with success. In the meantime I had sent unstained films to Professor Laveran, (7) to whom I am much indebted for his kindly interest, and who, in the *Proceedings of the Biological Society of Paris* of February 24th, describes the stained trypanosome, which he regards, provided further experiments prove it to be peculiar to cattle,[1] as a new species, and which, on account of its small size, he has named *T. nanum*.[2]

His interesting description of these parasites is as follows:—

"The trypanosomes measure 10 to 14 μ in length, by $\frac{1}{2}$ to 2 μ in breadth. Their structure is that of the flagellates of the genus *Trypanosoma*, although, contrary to the rule, the protoplasm is prolonged on the anterior part in such a way that there is no free part of the flagellum, or the free part of the flagellum is extremely short. The undulating membrane is very straight, and in consequence but little apparent. The posterior extremity is conical, not drawn out, and in other respects varies somewhat. The oval nucleus is situated near the centre of the body of the parasite. The rounded centrosome, rather large, occupies a position close to the posterior extremity. The protoplasm is homogenous without granules.

"Some forms a little longer than the others show two centrosomes and a flagellum, divided to a greater or less extent, proceeding from the centrosomic insertion."

He proceeds to point out how different in morphology is this trypanosome from *T. brucei* and *T. evansi*. He compares it with *T. theileri*, the giant trypanosome of South African cattle, and concludes by remarking that while very distinct from *T. theileri*, *T. nanum* approaches it in being peculiar to cattle, so far as is at present known.

I have little to add to the above description.

The photo-micrograph (Plate III., fig. 3), for which I am indebted to Dr. Beam, Chemist to the Laboratories, gives a very fair idea of *T. nanum*, multiplied 1,250 diameters. It shows it to be a short trypanosome with hardly any free flagellum visible, but is not quite typical, in that the posterior moiety is rather broader than is usually seen.

I append measurements I have made of a form whose total length was 14 μ.

From posterior end of body to centre of centrosome	1·2 μ
From centre of centrosome to nucleus ...	4·2 μ
Nucleus	1·6 μ
From nucleus to beginning of flagellum	5·6 μ
Free flagellum	1·4 μ
Breadth behind nucleus	2 μ

I agree that the protoplasm is homogeneous, though it sometimes stains irregularly, as evidenced (Plate III., fig. 3), while in forms kept *in vitro* granules appear, for the most part anterior to the nucleus. In such forms the vacuole in the neighbourhood of the centrosome may be found large and very evident. Sometimes a portion of the free edge of the undulating membrane is clearly visible, bunched, as it were, upon the back of the trypanosome, and looking like a loop. As a rule, however, the undulating membrane can scarcely be seen, save in the living parasite. I have worked with specimens stained by the Leishman-Romanowsky method, which answers admirably if the stain be strong and staining prolonged.[3]

I have carried out a few experiments *in vitro* which may be mentioned here, though the study of the trypanosome is yet far from complete, owing to lack of material and press of other work. Hence cultivation experiments have not yet been attempted.

In citrated blood kept at a temperature of 22° to 23° C. no change in the trypanosome was visible after twenty-four hours. They remained lively and stained well. After seventy-two hours at a temperature of 25° C. changes were observed to have occurred, the posterior ends of the parasites having become swollen, while the organisms were sluggish and evidently degenerating.

Trypanosomes disappeared in twenty-four hours from sterile citrated blood which had been exposed to a temperature of 16° C.

The trypanosomes from the Melut cow remained alive in non-sterile citrated blood at a temperature of about 35° C. for twenty-four hours. They underwent longitudinal division, forms with two centrosomes and two nuclei being seen. In these the undulating membrane was more apparent than usual.

Inoculation Experiments.—From Ox. No. 1, 0·5 cc. citrated blood, *i.e.*, about 0·25 cc. blood, was inoculated subcutaneously into a monkey (*Cercopithecus sabaeus*) on October 30th, 1904.

On the same date a rabbit received 1 cc. of citrated blood. These animals never show any symptoms of the disease, and though their bloods were repeatedly centrifuged in the hæmatocrit tubes, and carefully examined both in the fresh and stained condition, no trypanosomes were found.

From Ox No. 4, on November 23rd, a rabbit received 2 cc. of blood containing a considerable

[1] I have since found a very similar parasite in the blood of mules.

[2] *I.e.*, the "dwarf" trypanosome.

[3] Equal parts of thefluid stain and distilled water allowed to act for twenty minutes or even longer.

number of trypanosomes, six to the microscopic field (employing Leitz obj. 6, oc. 4, without ocular diaphragm), and a monkey (Cercopithecus) received 1 cc. The result in the case of these animals was also negative, though they remained under observation for two months.

On December 4th a brown pariah dog received 2·5 cc. of fresh blood subcutaneously at a time when trypanosomes were fairly numerous.

A black pariah dog received as food large pieces of the liver and spleen and several of the large glands, all soft food be it noted.

These experiments also proved absolutely negative.

On December 29th the last-mentioned rabbit happened to be killed accidentally. A *post mortem* was performed immediately, but no trypanosomes were found in the blood or in any of the organs. It would appear, then, that dogs, rabbits and monkeys (Cercopithecus) are not liable to infection with *T. nanum*. As it was desired to institute further experiments, the cow from Melut was brought to Khartoum, arriving there on March 4th, 1905, along with her calf. The blood of both animals was examined, but no trypanosomes were present.

In the case of the cow this fact, taken in conjunction with what was found in Ox 3, seems to prove that the parasites are in the habit of disappearing from the peripheral blood. Possibly spontaneous cure may occur.

The cow was in very poor condition, and presented all the symptoms of the disease, but repeated centrifuging of considerable quantities of blood failed to reveal the parasite. The animal has been under observation for nearly a month, and trypanosomes have never been demonstrated. Later examinations made down to the end of June all proved negative, and the animal being well fed, steadily improved in health and appearance. On March 7th, 1905, 4 cc. of the cow's fresh blood was inoculated subcutaneously into her calf. At the time of writing (March 27th, 1905) trypanosomes have not been found in the blood of the latter. Nor were they discovered up to the time of the last examination in June. The fact that, as a rule, there are not many parasites in the blood of cattle makes the investigation of *T. nanum* rather a tedious matter, and explains to some extent the imperfections of the research which has so far been conducted.

(3) *The Disease in Mules.*—For the study of trypanosomiasis in mules there have been available the stained slides of blood prepared by Captain Head from mules which were brought from the Bahr-el-Ghazal. The main source of material was, however, found in the three mules suffering from the disease at Taufikia. As stated, a dog was inoculated from one of these animals and brought to Khartoum, where it developed the disease. In the mule the chief symptoms of infection are the hanging head, the dull and listless eye, the roughened, staring coat, the prominent ribs, the general aspect of hopeless resignation, and the hind-leg projected from the body, a sign of weakness and giddiness. The blood of the mules seen at Taufikia literally swarmed with trypanosomes, and was thin, greasy, and difficult to spread on the slide. One animal died, but had decomposed before we got word of its decease. The death of a second enabled a *post mortem* to be performed. The most marked change was in the meninges, which were much thickened, the dura being very adherent to the skull. The brain was congested, and the cerebral vessels were gorged with blood. Elsewhere but little was found, the spleen not showing any increase in size or marked congestion. The liver was fatty. Unfortunately the stomach was not opened, a regrettable oversight on my part. It looked healthy viewed externally. There was no gelatinous, subcutaneous exudation, nor was the connective tissue œdematous. From the third mule the dog was inoculated, about 4 cc. being given subcutaneously on January 16th, 1905. On January 22nd trypanosomes were for the first time found in this dog's blood.

Slides of the mule's blood were sent to Professor Laveran, who describes the forms found in the same article as that in which he deals with *T. nanum*, the cattle trypanosome.

After remarking that the parasites were very numerous, he proceeded to distingush two types (fig. *A*):—

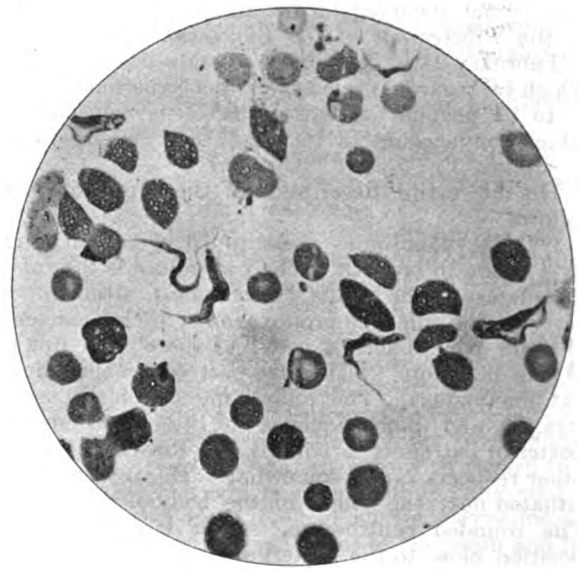

Fig. *A*.

(*a*) " Small forms measuring 12 to 14 μ in length, by $1\frac{1}{2}$ μ to $2\frac{1}{2}$ μ in breadth. These trypanosomes recall very much the appearance of the small forms of *T. dimorphum*. The protoplasm is prolonged as far as the extremity of the flagellum, which in consequence does not exhibit a free part. The undulating membrane is more developed than in *T. nanum*, but causes the parasite to present an even more ' stumpy ' aspect. The nucleus is situated sometimes in the centre, sometimes at the junction of the posterior with the middle third. The protoplasm contains chromatin granules, and these are sometimes very numerous. Forms in process of division are encountered with two centrosomes and one nucleus, two centrosomes and two nuclei, &c.

(*b*) " Large forms measuring 21 to 30 μ in length, by 2 μ in breadth. These forms, in which the flagellum

exhibits a very long free portion, bear a great resemblance to *T. evansi*. The posterior extremity is usually elongated, the protoplasm is homogeneous and with but few granules. Forms undergoing division by separation into two elements are found. It is to be noted that intermediate forms between the small and large trypanosomes are wanting."

From a study of numerous preparations, both fresh and stained, I am in a position to add a few additional notes to the above. In fresh blood both forms of trypanosome can be clearly made out. The long forms are much the more active, darting rapidly hither and thither, lashing vigorously with their flagella and displacing the red corpuscles. They can advance with either the anterior or posterior end in front, though their longer excursions are made with the flagellum "going on before."

Occasionally one of these long active forms may be seen to traverse the field of the microscope, but this is not common. The body of the trypanosome frequently

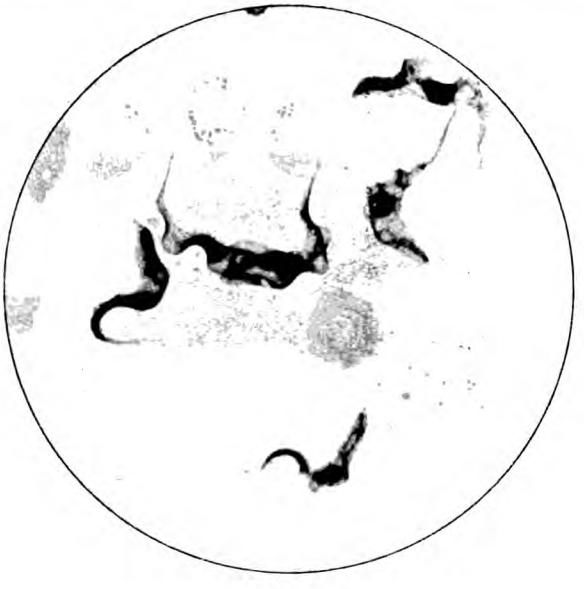

FIG. *B*.

bends upon itself, so that it presents the appearance of a tiny corkscrew for the fraction of a second—then stretching out, the parasite shoots across some space amongst the corpuscles, and plunges, writhing and lashing, amongst a startled group of erythrocytes. In the fresh state the undulating membrane is not very well defined in these long forms. They do not present a granular aspect. The short forms, on the other hand, are, as a rule, distinctly granular, and are more sluggish in their movements. They tend to hang about the same spot, and their excursions are limited, rather resembling those of *T. nanum*. They also can advance with either end in front, but their body movements are more of a rippling or undulating type. It often looks as though a series of shivers was running along the protoplasm. Their undulating membranes are well marked, and the rounded posterior ends are very distinct. On staining with Leishman-Romanowsky, used strong and for a considerable time, as in the case of *T. nanum*, the differences in structure between the two forms are well emphasised. Points to which Laveran, in his short note, does not refer is the well-known "pike-head" form of the posterior end of a typical long trypanosome, and the fact that the centrosome of the long form is not as large as that of the small. In some of the short forms the nucleus seems almost to touch the centrosome, while "bunching" of the undulating membrane is often well seen. I have noted curious forms, possibly distorted, with square-cut posterior ends, and more than once have seen a short form with no granules visible.

As a rule the granules are in the posterior moiety, *i.e.*, between the nucleus and the centrosome. In some instances the possession of these chromatin granules is almost the only point enabling one to distinguish this trypanosome from *T. nanum*. I have also noticed dividing forms, and it is not uncommon to find two short forms lying with their posterior ends in close contact, this being probably the terminal stage of a division (fig. *B*.).

In the mule's blood I did not observe conjugating or agglutinating or involution forms. I agree that the long forms measure from 21 μ to 30 μ, but some are as narrow as 1·4 μ at their thickest portion.

I append a very average set of measurements:—

From posterior end to centrosome ...	2·8 μ
From centrosome to nucleus	7 μ
Nucleus	2·8 μ
From nucleus to root of flagellum... ...	4·2 μ
Flagellum	6 to 10 μ

There is much variation amongst these long forms, but as a general rule the flagella stain admirably and complete measurements can easily be made.

Here are the figures for one of the short forms of a total length of 14 μ in which the nucleus was at the junction of the posterior and middle thirds:—

From posterior end to centrosome ...	1·4 μ
From centrosome to nucleus	1·4 μ
Nucleus (large)	2·8 μ
From nucleus to root of flagellum ...	7 μ
Flagellum	1·4 μ

I have found short forms to vary in length from 12 μ to 15·4 μ, and in breadth from 1·4 μ to 2·5 μ. As Professor Laveran points out in *T. dimorphum*, the trypanosome of horses in Senegambia, there also exist two forms, a long and a short. He asks if this and the mule trypanosomes are identical. He regards this as possible, but mentions the fact that while the short forms of the mule trypanosome resemble the short forms of *T. dimorphum*, the long forms of the former differ a little from those of the latter, mainly as regards the flagella, which as a rule are short in *T. dimorphum*. He adds, however, that variations occur, and that Dutton and Todd have described free flagella in the large form of *T. dimorphum*. Not only are they described but they are figured both in photo-micrographs and coloured plates, and I must say that my first impression was that I was dealing with *T. dimorphum*, or something very like it. To my mind the long forms more resembled the long forms of *T. dimorphum* than they did *T. evansi*, but then my comparisons were made from photographs and coloured drawings. Laveran

goes on to state another hypothesis, namely, that the mules may have been infected with two different species of trypanosome, and he cites the work of Cayalbon who, in the French Sudan, found horses to be the victims of a double infection (8).

There seems no reason why this might not occur as regards the short forms: one at once thinks of *T. nanum*, as the mules had come from the Itang district along with the herd of cattle amongst which was the cow harbouring those flagellates, and which aborted and died as already described.

In order to try and settle this vexed question, if possible, without proceeding to cultivation methods, and also to enable one to test certain therapeutic measures, animal inoculations have been conducted.

I do not propose to consider these in detail. Dogs, monkeys (Cercopithecus), gerbils, jerboas, rabbits and a goat were employed and numerous experiments were performed. As a result, I was led to think that these mule trypanosomes were really *T. dimorphum*, but this belief has been somewhat shaken by the discovery of a small trypanosome existing by itself in the blood of mules coming from the Bahr-el-Ghazal. It is difficult to be certain, and in any case the tendency is to follow Koch (9) and pay less attention to differences in species, and more to the presence or absence of pathogenicity.

(4) These inoculation experiments served to show how frequently ulceration of the gastric and to a less extent the intestinal mucous membrane was present *post mortem*. References to such a condition are not wanting in the literature. Dutton and Todd (10) found stomach lesions in a baboon dead of trypanosomiasis, while Musgrave and Clegg (11) record the presence of intestinal ulcers and ulcers in the cæca of animals dead of surra in the Philippines.

As a rule, however, attention does not seem to have been paid to the condition of the alimentary tract, and, as far as I know, when lesions have been noted smears have not been taken nor any further examination performed.

My number of *post mortems* in the cases of experimental animals now totals seventeen, and in nine of these gastric congestion or ulceration or both were present. In one case there was a marked ulceration of the cæcum and lower end of the ileum, in another Peyer's patches were congested. I do not think this can be a mere coincidence. A similar condition was found in the stomach of a Shilluk ox infected with *T. nanum*, and I am inclined to think, especially since hearing of Lieut. Gray's observations, that such lesions will be found to be common in trypanosomiasis.

As to their significance, one scarcely likes to hazard an opinion, but the thought that naturally arises is whether this condition may not indicate an effort on the part of the parasite to leave its host. Biting flies are regarded as the usual medium by which trypanosomes leave the body of an infected animal, though Rogers (12) has shown that the ordinary house-fly will serve the purpose in the case of open wounds, and fleas and other blood-sucking insects are effective as agents of transmission.

At the same the life-history of the trypanosomes of mammals is still obscure, and, so far as I know, despite the recent work of Koch at Ubebe, it has never been definitely settled whether or not they pass a stage in the flies or other insects which serve as carriers. I understand that Lieut. Gray's recent work in Uganda bears on this subject, but I have not had an opportunity of seeing it. It is, then, not possible that the parasite may escape from the body in some different manner? If so, may the gastric and intestinal lesions not be evidence of such exit? The condition found in cachexial fever due to the Leishman bodies will at once occur to any interested in this important subject. At the same time, we are immediately met with the argument that no one has ever found trypanosomes in the stools of infected animals, nor have such stools been definitely shown to be capable, on injection, of producing the disease. Lingard, it is true, states the contrary, but he is generally regarded as having been mistaken, and Musgrave and Clegg, who paid special attention to this point, deny that the stools can convey infection. Rogers also refutes Lingard's contention. In the face of all the evidence which has been accumulated and the absence of any experiments with the stools of inoculated animals, one is not justified in putting forward any theory.

(5) It is, however, interesting to note that on several occasions, both in the case of dogs and of monkeys, spirilla (fig. *C*) have been found in the blood clots

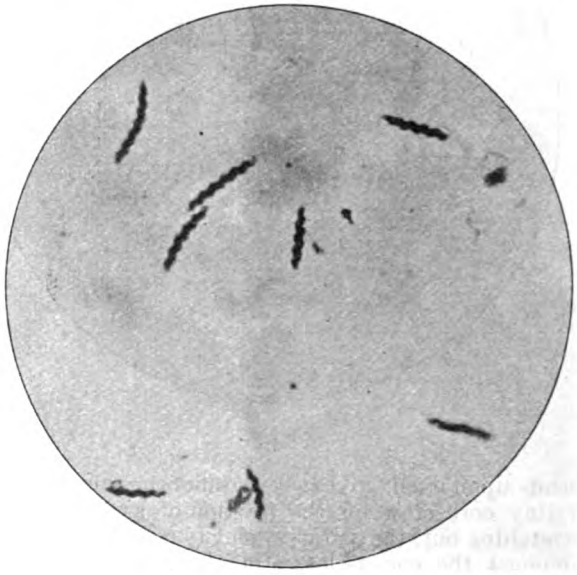

FIG. *C*.

covering the ulcers or in smears made from the ulcerated surfaces. These spirilla, which are somewhat blunt at the extremities, measure from 2·8 μ to 7·7 μ in length, are very actively motile, and possess from four to seven short undulations. There is a general impression found chiefly on Sohandium's (13) work, that trypanosomes and spirilla will be found to be very closely related, if they are not indeed merely different stages in the life of one parasite. Moreover, Theiler, in South Africa, has found trypanosomes and spirilla existing together in the blood of cattle, and Petri (14) has found the same thing in birds. The spirilla which I describe are short forms, and have not the typical

pointed ends of, say, *Spirochæte obermeieri*. For all that they are undoubted spirilla, and I have not found such present in the stomach or intestines of animals uninfected with trypanosomiasis. I think the observation is one of considerable interest. At present it is nothing more, but it seems worth while following up the matter.

(6, .7) The therapeutic value of chrysoidin and of blood serum. I propose to deal very briefly with these points in this paper. I was led to employ chrysoidin, a yellow aniline dye, and chemically the hydrochloride and di-amido-azo-benzene, because trypan red and malachite green had been used with some success, and because I had previously found chrysoidin (15) to be very lethal in dilute solutions to fish and to the ciliated embryo of *Schistosomum hæmatobium*. Further, I had found that it possessed, at least as regards fish, a special affinity for the central nervous system, staining the brain and spinal cord an intense yellow. I found the same to be true of the soluble form (chrysoidin extra), prepared by the Aniline Manufacturing Company, of Berlin, in the case of the gerbil (*Gerbillus pygargus*, Linn.).

For the most part I have used Merck's chrysoidin, ·1 grain of which in 10 cc. of distilled water constitutes a saturated solution.

Preliminary experiments *in vitro* showed that in a proportion of 1 in 500 it killed the trypanosomes of mules practically instantaneously, at the same time slightly colouring them. On staining such dead trypanosomes by the Romanowsky method they were found to take the colour badly and to have swollen posterior ends. They looked as if they had shrunk into themselves. In a strength of 1 in 6,000 some trypanosomes were observed to die in five minutes. Others though retaining their motility become rounded, and these also died after forty-five minutes. After four hours only one living trypanosome could be found. Though lively it had changed in shape and looked like an involution form. Although weaker mixtures, even 1 in 30,000, killed some of the parasites many were found to survive. In all cases controls were performed, and the blood was mixed with sterile citrate solution. No agglutination was observed. The dye was not so lethal as I had hoped, but I resolved to give it a trial, and employed it in the case of dogs, monkeys, and gerbils. Without entering into details, it may be said that as regards the trypanosome of mules the results have been somewhat disappointing. True the dye profoundly alters the parasites in the peripheral blood and sometimes causes their temporary disappearance, but I have been unable by its use to prolong the lives of infected animals or to greatly modify the course of the disease. It has been given subcutaneously and intravenously without marked smears, but it is worth while remembering that Laveran found *T. dimorphum* very resistant to the action of trypan red.

Dr. Neaves (16) employed chrysoidin in a case of human trypanosomiasis from Uganda, and found it caused the parasites, which were numerous, to disappear wholly from the peripheral blood and the juice of the affected cervical glands. I was able to confirm his observations, but succeeded in inoculating a monkey (Cercopithecus) by injecting several cc. of blood taken from a vein. The disease, therefore, was not cured, but the results have been somewhat hopeful, as the patient has greatly improved in condition (fig. *D*), and

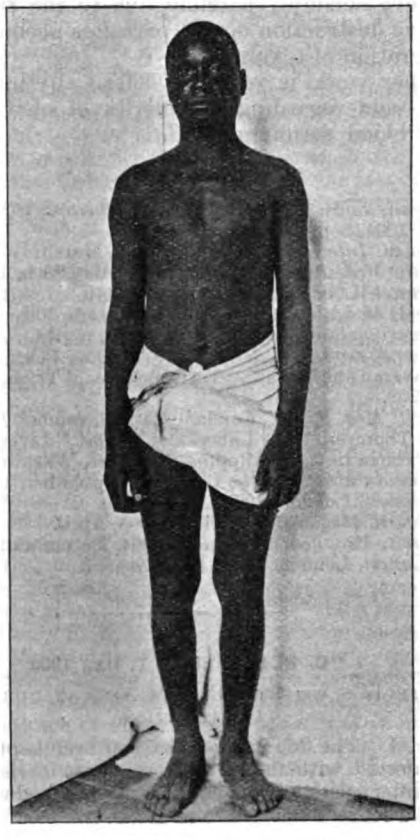

Fig. *D*.

chrysoidin does not cause the unpleasant staining of the mucous membranes which is one of the draw backs to the use of trypan red. The dye is easily given by subcutaneous injection, and, if it can so greatly diminish the parasites in the peripheral blood, may yet establish itself as a useful agent in preventing the transmission of the disease.

Dr. Neave proposed testing the therapeutic effect of the blood serum of wild animals from trypanosome-infected districts on experimental animals inoculated with trypanosomiasis. He sent me a sample of blood serum from a water-buck free of trypanosomes. It arrived in good condition, a small quantity of carbolic acid having been added to it as a preservative.

I proceeded to test it *in vitro*, and found that, added in equal quantities to citrated blood containing the trypanosomes of mules, it caused agglutination in the form of irregular rosettes, the motility of the trypanosomes composing the rosettes remaining. After thirty minutes there was marked agglutination. Disintegration and death of the parasites also occurred.

I employed the serum in varying doses in the case of monkeys and gerbils, and in some instances found that it produced a remarkable effect on the parasites, completely disintegrating them, so that on staining

nothing was to be seen except the centrosomes with flagella attached.

Here again, however, I have been unable to modify the disease or prolong life. Indeed, large doses of the serum have apparently hastened the end, producing convulsive seizures, possibly due to the sudden and extensive destruction of the parasites accompanied by the liberation of toxins.

Further work is required before anything definite can be said regarding the merits of chrysoidin and of this blood serum method.

SOME ATTEMPTS TO CULTIVATE THE BACILLUS OF LEPROSY.

Neil, Emile M. P., claims to have cultivated the *B. lepræ* outside the human body but could not maintain his cultivations. More or less success was obtained with a variety of media, but the most successful was a bouillon made with 250 grms. of veal in 750 grms. sea-water and 250 grms. distilled water. Make distinctly alkaline, and add 40 grms. of glycerine, 8 of glucose, 10 of peptone and 20 of agar. Place in the cooler and add 1 part of yolk of egg to 4 parts of gelose in each tube.

FLAGELLATE PARASITE FOUND IN CULEX FATIGANS.

Ross, Major Ronald, C.B., F.R.S., recalls certain observations made by him in 1898 on certain "amœbulæ and flagellulæ," found in the intestines of mosquitoes, and suggests that the organisms found in mosquitoes by Schaudinn, and believed by him to be a stage of the *Halteridium danilewskyi* of the little owl may really be quite distinct parasites, having no connection with the avian hæmatozoon.

It is obvious, however, that it is equally possible that the protozoa referred to by Professor Ross may not, as he supposes, be purely mosquito parasites, but may really be a developmental stage of the hæmatozoa of some vertebrate. The question, however, may be safely left for the two distinguished protozoologists to discuss and settle between them.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

Journal of Tropical Medicine

MARCH 15, 1906.

LIVERPOOL SCHOOL OF TROPICAL MEDICINE.

REPORT FOR 1905.

THE Seventh Annual Report of the work of this School shows that it continues to fulfil, in an eminently satisfactory and creditable manner, the purposes for which it was founded.

Whether regarded from the point of view of the practical and scientific training it affords to a large number of medical men, or the yet higher platform of original research, the School authorities have every reason to be satisfied and proud of their achievements. The publications emanating from the School have advanced our knowledge in many directions, and enhanced the reputations of the several contributors.

The "Mary Kingsley Medal" has been bestowed by the School authorities upon Sir Patrick Manson, K.C.M.G., F.R.S.; Colonel David Bruce, C.B., F.R.S.; Dr. Laveran, and Professor Koch. The Liverpool School of Tropical Medicine has sent out expeditions to several parts of the Tropics, costing some valuable lives, and involving the expenditure of large sums of money. So important have these expeditions proved that the publication of a complete list of the several

undertakings is deemed worthy of being reproduced, as a testimony of their consequence and of the success attending them.

EXPEDITIONS.

The First (Malarial) Expedition: Major Ronald Ross, C.B., F.R.S., Dr. H. E. Annett, Mr. E. E. Austen (of the British Museum) and Dr. Van Neck (of Belgium), despatched to Sierra Leone in the summer of 1899.

The Second (Malarial) Expedition: Dr. R. Fielding Ould, despatched to the Gold Coast and Lagos, in the winter, 1899.

The Third (Malarial) Expedition: Dr. H. E. Annett, Dr. J. E. Dutton and Dr. Elliott, despatched to Northern and Southern Nigeria in the spring of 1900.

The Fourth (Yellow Fever) Expedition: Dr. H. E. Durham and the late Dr. Walter Myers, despatched to Cuba, and to Para in Brazil in the summer of 1900.

The Fifth (Sanitation) Expedition: Major Ronald Ross, C.B., F.R.S., and Dr. Logan Taylor, despatched to Sierra Leone in the early summer of 1901.

The Sixth (Trypanosomiasis) Expedition: Dr. J. E. Dutton, despatched to the Gambia in the autumn of 1901.

The Seventh (Malarial) Expedition: Dr. C. Balfour Stewart, despatched to the Gold Coast in November, 1901.

The Eighth (Sanitation) Expedition: Major Ross, despatched to Sierra Leone on February 22nd, 1902.

The Ninth (Malarial) Expedition: Major Ross, accompanied by Sir William Macgregor, K.C.M.G., the Governor of Lagos, despatched to Ismailia, September 11th, 1902.

The Tenth (Trypanosomiasis) Expedition: Dr. J. E. Dutton and Dr. J. L. Todd despatched to the Gambia and French Senegal on September 21st, 1902.

The Eleventh (Sanitation) Expedition: Dr. M. Logan Taylor, despatched to the Gold Coast from Sierra Leone on October 11th, 1902.

The Twelfth (Trypanosomiasis) Expedition: Dr. J. E. Dutton, Dr. J. L. Todd, and Dr. C. Christy, despatched to the Congo Free State on September 23rd, 1903.

The Thirteenth Expedition: Professor Rupert Boyce, M.B., F.R.S., Dr. Arthur Evans, M.R.C.S., and Dr. Herbert H. Clarke, M.A., B.C.Cantab., were despatched to Bathurst, Conakry and Freetown on November 14th, 1904, to report on the Sanitation and Anti-malarial Measures in practice at the towns visited.

The Fourteenth Expedition: Lieut.-Col. G. M. Giles, M.B., F.R.C.S., Indian Medical Service (Rtd.), and Dr. R. Ernest McConnell, M.D. (Canada), despatched to the Gold Coast on December 31st, 1904.

The Thirteenth and Fourteenth Expeditions were sent to West Africa in appreciation of Sir William MacGregor's great services to health and sanitation in West Africa.

The Fifteenth (Yellow Fever) Expedition: Dr. H. Wolferstan Thomas and Dr. Anton Breinl, despatched to the Amazon in April, 1905. Both members of the Expedition contracted yellow fever and Dr. Breinl had to be invalided home.

The Sixteenth (Yellow Fever) Expedition: Professor Boyce, F.R.S., despatched to New Orleans in August, 1905, to observe the work of the United States Medical Authorities in dealing with the outbreak of Yellow Fever there. Professor Boyce subsequently visited British Honduras at the special request of the Colonial Office, to make a report on the conditions existing in that Colony with reference to a recent outbreak of Yellow Fever.

The paragraph in the Report referring to the death of Dr. J. E. Dutton, whilst engaged upon scientific work on the Congo, is a fitting testimony to a distinguished man who lost his life in the cause of humanity.

THE LATE DR. J. E. DUTTON.

It was with the deepest regret that the Committee learned of the sudden death of Dr. Dutton, Walter Myers Fellow, at Kosongo, on the Congo, on February 27th, while actively engaged in the investigation of trypanosomiasis and tick fever. In 1903, Dr. Dutton, accompanied by Dr. Todd, proceeded to the Congo to investigate trypanosomiasis and other tropical diseases. Towards the end of 1904 they had reached Stanley Falls, and independently they were able to demonstrate the cause of tick fever in man—a discovery made a few weeks previously by Ross and Milne in the Uganda Protectorate. Further, they were able to prove the transference of the disease from man to monkeys by means of a particular species of tick. During these investigations both observers contracted the disease. The last letter received from Dr. Dutton was dated Kosongo, February 9th, when he seemed in excellent spirits. In his death, the Tropical School and the University have suffered the loss of a most brilliant graduate. Although only twenty-nine years old, he had already won a recognised position throughout the scientific world.

Educated at the King's School, Chester, Dr. Dutton proceeded to the University of Liverpool, where he rapidly made his way, and in 1897 he was appointed to the George Holt Fellowship in Pathology, which gave him the opportunity for research. Dr. Dutton entered the Royal Infirmary, where he acted as house surgeon to Professor Rushton Parker and house physician to Dr. Caton. In 1901 he was elected to the Walter Myers Fellowship in the Tropical School. His first expedition to West Africa took place in 1900 when, with Dr. Annett, he visited Nigeria. In 1901 he proceeded alone to the Gambia, and drew up a most comprehensive and useful anti-malarial report which has proved of the greatest service to that colony. It was during this expedition that he identified in the blood of a patient of Dr. Forde, the Medical Officer of Bathurst, a trypanosome belonging to a group of animal parasites which had hitherto been found only in animals. He accurately described and named it. Subsequently he found the same organism in numerous other patients in the Gambia and elsewhere. It can hardly be doubted that this brilliant discovery of the first trypanosome in man by Dr. Dutton was an important step in leading to the discovery of the cause of sleeping sickness, which was subsequently shown by other observers to be due to the same parasite. In addition to his discovery of *Trypanosoma gambiense*, he also described several other trypanosomes new to science. In 1902 he proceeded with Dr. Todd to Senegambia, and drew up a report on sanitation, which was presented to the French Government, and further papers on trypanosomiasis which were published. The present expedition to the Congo was sent out in 1903. Dr. Dutton was accompanied by Dr. Todd and Dr. Christy, the latter returning to England in June last.

It will be seen from this account that, although only twenty-nine, Dr. Dutton had accomplished a vast amount of useful work, and had advanced in a most striking manner our knowledge of medicine. Medical science has lost one of its most promising and distinguished men. The City of Liverpool mourns the loss of one of its most gifted students, and his colleagues in the University and the Royal Infirmary have lost one who combined with a great intellect a charming personality, which made him beloved by all.

About 900 cases of various tropical diseases have been treated at the special ward of the School in the Royal Southern Hospital since the School's opening, including cases of sleeping sickness. Students receive their clinical instruction in this ward.

Students to the number of 150 have already taken out the course of instruction. These students have been medical officers of nearly every nationality, and in almost every case have been men holding responsible official positions in tropical countries, who have realised the value of what may still be considered as a new departure in medical research.

Reviews.

LECTURES ON TROPICAL DISEASES. Being the Lane Lectures for 1905. Delivered at Cooper Medical College, San Francisco, U.S.A., August, 1905. By Sir Patrick Manson, K.C.M.G. London: Archibald Constable and Co., 16, James Street, Haymarket, S.W. 1905. Pp. 230. Illustrated. Price 7s. 6d.

Every medical man interested in tropical medicine will welcome this volume. It is needless to say that the subject is presented in that fascinatingly educative style of which Sir Patrick Manson is master. Not only are the several diseases described with accuracy as regards their pathology, etiology, prophylaxis and therapeutic treatment, but from the first to the last page the subject matter is presented in a form which teaches one to regard tropical pathology, and all that appertains to it from the higher platform of public health and racial welfare. Of the ten chapters, under which the lectures are arranged, the first six are devoted to descriptions of such diseases as Epiphytic Disease of the Skin, Ankylostomiasis, Dracontiasis, Endemic Hæmoptysis, Bilharziosis, Filariasis, Malaria, Trypanosomiasis and Sleeping Sickness; Kala-Azar and other diseases of lesser importance in regard to their epidemicity. Chapters VII. and VIII. deal with the Diagnosis of Tropical Fevers; Chapter IX. is concerned with Treatment. The last chapter is the one to which medical men, acquainted with tropical ailments, will turn, namely: "Problems in Tropical Medicine." Under this heading the reader will find a wealth of suggestions and scientific deductions which must prove stimulating to thought and research. Yellow Fever, seeing that the lectures were delivered to an American audience, naturally occupies considerable space in the matter of "Problems," but the treatment of this subject has direct bearing upon the principles to be followed in research in other diseases and in other countries. Sir Patrick, discussing the Creole immunity to yellow fever, adopts "as a working hypothesis that there are two strains of yellow fever virus, one of great virulence, one of little virulence. Specifically the same, they are mutually protective. They differ only in their respective pathogenicity. The relationship pertaining between them recalls that between small-pox and vaccinia, and the native in the endemic area acquires his immunity against the virulent disease from having had the non-virulent disease already." It is useless, however, attempting to quote jottings from a book which is a consecutive whole, and every word of which is interesting, educative, and a stimulant to the pursuit of research and observation. The book will remain a classic, long after many of the subjects it deals with are further elucidated, for the store of knowledge it embraces and the suggestions as to future investigations it contains are no mere ephemeral speculations, but deductions founded on a logical basis which increased knowledge may prove to correct but cannot upset.

THE WEST AFRICAN POCKET BOOK.

The West African Pocket Book is a happy idea. It is not merely in name but in form and style a pocket book which any one travelling can always carry about in the pocket. We have nothing but praise for its contents. It is intended as a guide for newly appointed Government officers, and has been compiled by direction of the Secretary of State for the Colonies. Within fifty-nine pages it gives concisely and in simple language excellent information and directions as to outfit, personal hygiene, food and drink, care of quarters, travelling and bush life, precautions to be taken against malaria, and treatment of some of the more common diseases and accidents when the help of a medical man cannot be obtained. The pocket-book is worthy of every commendation, and the Colonial Office are to be congratulated on its issue. It is to be obtained from Waterlow and Sons, London.

Correspondence.

THE TEETH OF CENTRAL AFRICAN NATIVES.

To the Editor of the JOURNAL OF TROPICAL MEDICINE.

SIR,—In your issue of October 2nd last there are some remarks by a Dr. G. A. P. Ross on the teeth of Central African natives. I did not see the article to which he refers; I have not long been a subscriber to your Journal.

I beg to correct the following statement with reference to the Angoni tribe: viz., "Their food is entirely vegetable, consisting of rice, mealies, and ufa (mealies and Kaffir corn mixed.)"

Probably the older of the men he examined had never heard of rice in their boyhood. Until a few years ago rice was only grown at one station on the western shore of Lake Nyassa, where its cultivation was probably started (and certainly encouraged) by H.M. Administration.

The Angoni are almost entirely confined to the highlands, where they can hardly grow rice, so it must be rarely that rice enters into the Angoni villager's diet. Of course as a European carrier rice would be the usual ration.

Presuming "mealies and Kaffir corn" to mean Indian corn and millet respectively, it does not follow that because these are their ordinary food that they take them mixed and call it "ufa," as the writer states. "Ufa" is simply the native name for flour, and may be made from maize, millet, or other smaller native grain. This flour, with beans, vegetable marrows, wild green herbs, and whole maize roasted as a cob in the embers of a fire, or as separated grains on a shovel, like coffee-beans often are, is the daily dietary of natives in the villages.

Again, they are not vegetarians from choice: they keep goats and pigs, and some have sheep and cattle, while their poultry sleep in their houses with them; and not only do they eat meat whenever they can get it, and eagerly join a shooting party as carriers, but one may often see a gang of Angoni labourers after the day's work hunting the grass for field rats and mice for the evening stew-pot, and Europeans' cats often disappeared for the same purpose.

It will be seen, therefore, that it is rather because practically the whole grain is eaten by natives, and to their care of the teeth, than to absence of meat from their diet, that must be held to account for the high percentage of good teeth amongst Central African natives.

I am, &c.,

East Africa, J. E. S. OLD, M.D.
February 6th, 1906.

ABSENCE OF FEVER IN QUARTAN MALARIA.

To the Editor of the JOURNAL OF TROPICAL MEDICINE.

DEAR SIR,—Reading the interesting remarks of Dr. Wellman in your issue of February 1st ult., concerning absence

of fever in quartan malaria, the following observations may be of interest.

This country varies enormously in the malarial index in different parts, the index being 100 per cent. to 80 per cent. in low-lying, wet situations and in parts of Jerusalem; in the upland villages Ramallah, for instance, the splenic index, is only 4·3 per cent. (in 232 children, 10 years and under).

(1) A Jewish woman, showing quartan rosettes in the peripheral blood *in hospital*, had had no fever for several days; the spleen was considerably enlarged, and there was well-marked cachexia.

(2) A girl of 12 years or so, after severe attacks of fever, denied any rise of temperature for over two months; she was very cachectic, had enlarged spleen, and showed numerous pale rings and crescents in the blood.

(3) Two other patients, showing sparse quartan and tertian parasites, had had no fever for *ten* and *twelve days* respectively.

(4) A healthy European, engaged in archæological work, on *the first day of fever* showed numerous tertian forms, including spores and equally numerous gametes. This leads to an interesting query as to the date of appearance of gametes in tertian fever; so far as I have seen, crescents are not seen until seven days from onset of fever. This patient had had no fever for months to my knowledge.

Another point of interest is, that whereas malaria is very little in evidence in winter (one case per diem or less), almost all of these have proved to be quartan in character under the microscope, and Dr. Masterman, working in Jerusalem, has noted the same in a marked manner, from clinical evidence. In this country there would seem to be no preponderance of tertian fever in spring, as in Italy, or of subtertian malaria in autumn, when tertian fever is commonest.

I am, yours faithfully,

Ramallah, Jerusalem,
February 15th, 1906.

JOHN CROPPER.

Drugs and Remedies.

PREPARATIONS BY MESSRS. PARKE DAVIS AND CO., 111, QUEEN VICTORIA STREET, LONDON.

(1) *Fluid Extract of Cassia Beareana.* — This species of cassia, introduced by Dr. O'Sullivan Beare, has obtained considerable reputation as a therapeutic agent in the treatment of blackwater fever and of ordinary malaria. Messrs. Parke Davis have prepared a fluid extract which ensures stability of dosage and portability without deterioration.

(2) *Antimalaria Tablets.*—Each tablet contains: quinine sulph., 3 grains; powdered nux vomica, gr. ¼; powdered capsicum, gr. ½; and extract of hyoscyamus, gr. ½. The components of this tablet are eminently suitable for tropical residents; the introduction of capsicum harmonises with the ideas entertained by native practitioners in the Tropics as to the virtues of "spices" in decoctions prepared by them.

(3) *Warburg's Tincture Tablets.*—Each tablet represents a fluid drachm of the Warburg's well-known tincture. There can be no doubt of the efficacy of Warburg's tincture in the treatment of febrile ailments in tropical countries, more especially when marked gastro-hepatic derangements accompany the illness. Its efficacy in remittent malaria is undoubted.

(4) *Acetozone* in solution is powerfully germicidal, and possesses the advantage of being non-toxic. At the strength of 1 in 1,000 in typhoid, 1 in 2,000 in dysentery and cholera, and 1 in 3,500 in intestinal fermentation, acetozone has proved highly beneficial.

(5) *Hæmabic Hypophosphites* is an elegant preparation, palatable and suitable in debility and anæmia, especially when these are the result of acute and subacute illnesses.

Notes and News.

BERMUDA.

The Medical Board appointed to enquire into the medical qualifications of persons desiring to register as medical practitioners in Bermuda consists of: Eldon Harvey, F.R.C.S.Eng., L.R.C.P.Edin.; Dudley Cox Trott, M.B., B.C.Cantab., F.R.C.S.Eng., &c., &c.; and William Eldon Tucker, M.B., B.C. Cantab., &c.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

Sec. I., "Kwai Medical Journal," Johan, December 31, 1905.

EXPERIMENTS ON DOGS DURING KAK'KE (BERI-BERI) INVESTIGATIONS.

Baron Takaki fed three dogs on vegetable diet (including rice) and three dogs on a diet containing beef. The dogs fed on vegetables only increased in weight markedly at first, but later became thin, feeble, lost sensation and motion in the hind limbs and died. The dogs fed on beef and vegetables gained in weight more slowly and remained healthy and strong. Takaki concludes that increase in weight is no evidence of health.

"Semaine Médicale," September 13, 1905.

MALARIAL PERITONITIS.

Gillot, V., describes a case of acute peritonitis occurring in a patient in whom the malaria parasite was found in the blood. The peritonitis yielded to treatment by quinine.

"Presse Medicale," December 30, 1905.

OVA IN THE INTESTINAL PARASITES; TECHNIQUE OF OBSERVATION.

Letulle, M., recommends for the diagnosis of the presence of ova in the fæces, that (*a*) in the case of a fluid stool, after centrifugalisation a drop of sediment is taken for examination; (*b*) solid fæces are first dissolved in water, and then treated as in the case of a fluid stool. The ova possible to isolate in this manner are those of (1) *Ascaris lumbricoides*, (2) *Oxyuris vermicularis*, (3) *Bothriocephulus latus*, (4) *Trichocephalus dispar*, (5) *Ankylostoma duodenalis*, and (6) *Bilharzia hæmatobium*. In his paper, Letulle gives careful drawings of the ova of these parasites.

"American Journal of Medical Sciences," January, 1906.

Thomas, J. B. Report on the action of various substances on pure cultures of the *Amœba dysenteriæ* and cholera spirilla. The following laboratory experiments by Thomas are interesting, and may be of clinical value:—

(*a*) The following retarded the growth of *Amœba dysenteriæ* and cholera spirilla in thirty minutes: Acid tannici, 1 in 100; quinine sulph., 1 in 1,000; cupri sulph., 1 in 2,000; potassium permanganate, 1 in 4,000.

(*b*) Retarded the growth within thirty minutes: Quinine sulph., 1 in 500; protargol, 1 in 500; argyrol, 1 in 500; potassium permanganate, 1 in 2,000; argenti nitrate, 1 in 2,000.

(*c*) Destroyed amœba in fifteen minutes, with only slight effect on cholera spirilla: Thymol, 1 in 2,500.

"Gazetta Degli Ospedali edelle Cliniche," January 7, 1906.

Conti, A. A clinical note in a case of chronic spasm of the region of the accessory nerve of Willis due to malaria.

"Journal American Medical Association," February 3, 1906.

(1) Wilkinson, H. B. "Leprosy in the Philippines, with an Account of its Treatment with the X-rays." Wilkinson finds that treatment of one leprous spot produces improvements in spots in other parts of the body which in their progress advance parallel to and just as complete as in the spot exposed to the X-rays. He therefore assumes that the leprosy bacilli are killed by the treatment, and that their bodies, reabsorbed into the blood, are the immunising and curative factors. He finds the more pronounced the cure the better does the X-ray treatment serve—a phenomenon he explains by the fact that the more pronounced the disease the more bacilli are present, and, therefore, the more immunising agents, in the form of dead bodies of bacilli, are produced. A parallel immunisation is that provided in plague by using injections containing the dead bodies of the plague organisms; in the case of leprosy, however, as treated by X-rays, the culture medium is not produced in the laboratory, but is no other than the human body itself.

REPRODUCTION OF CLEPSIDRINA OVATA.

Schnitzler, H., continues the work of Pähler on the same species of gregarine, and concerns himself mainly with the details of the changes undergone by the nucleus after the encystment of the coupled adults. He describes the formation of a very small spindle of division in each nucleus when all the chromatin and the nuclear membrane have disappeared, and also the mitoses of the reproductive nuclei during division. He confirms, with further details, Pähler's description of the phenomena of nuclear reduction by the throwing out of a polar globule which characterises the maturation of the sporoblasts or gametes (a unique instance amongst the gregarines). Lastly, he figures and describes the isogamic reproduction of the gametes in pairs. Each couple gives origin to one of the cask-shaped sporocysts with eight sporozoites, which is a characteristic of the genus *Gregarina*.

He was, however, unable to work out the evolution of the other form of cyst which is formed by a single gregarine, but suggests that the difference in the size of the sporocysts is connected with these solitary encystments.

"Arch. Zool. Expér.," 4th Series, T. iv., 1905.

RESEARCHES ON THE REPRODUCTION OF THE MONOCYSTID GREGARINES.

Brasil, Louis, follows the development of these parasites from encystment to the formation of the sporocysts. He states that, at any rate, in the four species of Monocystis found in earth-worms which he has examined the gametes are anisogamic. In this they resemble two others of this genus infesting the body cavity of certain marine annelids. The author describes with great care the origin and structure of the asters, their division into two, the formation of the directive spindles, the elimination during the first division of a great part of the nuclear chromatin and the division of the residual chromatin amongst the daughter nuclei.

"Sitzungsber d. K. pr. Akad. d. Wiss.," T. xlvi., 1905.

SPECIFIC DISTINCTIONS BETWEEN TRYPANOSOMES.

Koch, Professor R., draws attention to the difficulties of distinguishing between trypanosomes generally, and especially of those that act as pathogenic organisms in mammals. Their pathogenic character cannot, however, be used to distinguish them, as the animal employed in such a test might have acquired immunity. The key of the difficulty, he believes, lies in comparing not merely the adult forms, but the various evolutionary stages which they undergo, As an example, he compares the evolutionary stages of *T. brucei* in *Glossina morsitans* and *G. fusca* with that of *T. gambiense* in *G. palpalis*. In both cases there are found in the digestive tubes of flies that have imbibed infected blood two very distinct forms: the one sort plump, with abundant, easily stained plasma and a round, spongy nucleus; the other elongated and thin, with scanty, ill-staining protoplasm and a dense, rod-like nucleus. Judging from analogy, the former are the female and the latter the male elements. Now the two species can easily be distinguished as follows:—

Female Forms.—T. brucei: Blepheroplast or centrosome round, and about 1 μ in diameter. *T. gambiense:* Elongated transversely, and 2·5 μ 5 by 1·5 μ.

Dimensions.—Female forms: *Brucei*, 25 μ by 3·6 μ; *gambiense*, 37 μ by 3 μ. Male forms: *Brucei*, 40 μ by 2·1 μ; *gambiense*, 34 μ by 0·85 μ.

"C. R. Soc. Biol.," T. lix.

FREQUENCY OF TRYPANOSOME INFECTION IN RATS AND MICE.

Sabragès, J., and Muratet, L. All the specimens of *Mus rattus* examined at Bordeaux were found to be infected, but none of those of *M. decumanus* or of mice. On the other hand, a big *M. decumanus* taken at Tours was found to be infected.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the JOURNAL OF TROPICAL MEDICINE should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communications.

ON A HEMIPTEROUS INSECT WHICH PREYS UPON BLOOD-SUCKING ARTHROPODS AND WHICH OCCASIONALLY ATTACKS MAMMALS (MAN).

By F. C. Wellman, M.D.

Benguella, West Africa.

Some months ago I mentioned (1) an insect, called by the Angola Bantus "*Ochindundu*," which preys upon blood-sucking ticks. The specimen upon which I based my remarks was taken in the act of feeding upon a very important tick of the region (*Ornithodoros moubata*) which is one of the carriers of human spirillosis. I have since learned that the insect itself inflicts a very painful and even dangerous bite. The specimen was sent to the British Museum, but, having heard nothing of it, I suppose it must have been lost *en route*. Since I have on several occasions referred to the insect (2), I shall here give (as well as I can in the absence of the anticipated report from the Museum and without access to a library) a few notes on the appearance, probable systematic position, bionomics, and pathologic significance of the animal.

Systematic Position and Description.

The insect under consideration belongs to the *Hemiptera* (Bugs) falling among the *Heteroptera*. Here it is to be placed with the *Geocores* (Land bugs), thus allying it with bed-bugs, squash-bugs, &c. It belongs to the family *Reduviidæ* (3). This family is related on the one hand to the *Nabidæ*, and closely on the other to the *Emesidæ*. The *Reduviidæ* are distinguished by having the front femora somewhat thickened, but much less than half as wide as long. Two ocelli are often present. The rostrum is short, three-jointed, attached to the tip of the head, and with the distal end, when not in use, resting upon the prosternum, which is grooved to receive it. The species are many. While I, of course, cannot definitely place

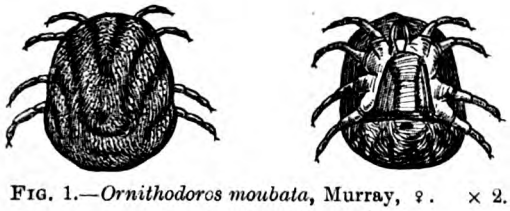

Fig. 1.—*Ornithodoros moubata*, Murray, ♀. × 2.

the species studied by me without access to descriptions and specimens of its allies, yet I have no hesitation in saying that it closely approaches *Reduvius* (*Opsicaetus*) *personatus*, *L.* I have no description of *R. personatus* by me, but my impression is that the first two pairs of legs in the last-named bug are less thickened than in the case of the "*Ochindundu*," and other differing anatomical details very possibly exist. The "*Ochindundu*" is, like *R. personatus*, black in colour, but the first two pairs of legs are of a bright red hue. I have recently captured a similar insect which is entirely red. I present a rough sketch (fig. 2) of the "*Ochindundu*," made when the bug was first discovered. Having, as I have said, sent the original specimen to the British Museum, I cannot offer a better drawing.

Bionomics.

The "*Ochindundu*" preys upon ticks, catching them and sucking, by means of its powerful piercing proboscis, the blood with which they have filled themselves. The insect is provided with curious paddle-like structures on its first four legs, which are

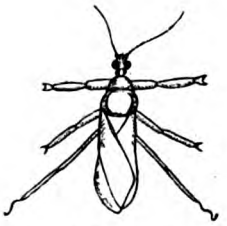

Fig. 2.—The "*Ochindundu*." Nat. size.

evidently designed for holding securely the tick upon which the creature feeds, the "*Ochindundu*" sitting, as it were, upon its hind pair of legs during the process. The attitude taken while sucking blood from a tick is shown in fig. 3. The only tick which I have actually seen in the clutches of the insect is *Ornithodoros moubata*, Murray. The substance of my note sent with the specimen forwarded to the British Museum is as follows:—

"I found this insect June 22nd, 1905, while studying the tick sent to the Museum some time ago (*O. moubata*, Murray). The bug was running about on the sticks composing a pig-sty where I was collecting ticks. My attention was attracted by its singular appearance and movements. Suddenly it entered a large crack in a stick and remained for some seconds. I could not clearly see what it was doing, so I had the stick split open, whereupon I found the insect in the position figured in the following sketch, holding a tick with its first four legs, and sucking blood from it, for which purpose it had inserted its proboscis deeply into the tick. The animal was so intent on its prey, that I was able to carry it to a house without disturbing it and to observe its actions for some time, and also to exhibit it in the act of sucking blood from the tick. When placed in a killing bottle, it withdrew its proboscis from its prey, but still clutched it with its legs. I mounted it in this position, and the wound may be seen in the tick near the margin of its body."

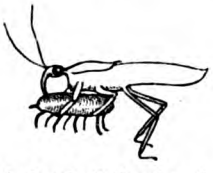

Fig. 3.—The "*Ochindundu*," showing the position it assumes in the act of sucking blood from a tick (*O. moubata*). Nat. size.

I have not determined its life-history. In some members of the *Reduviidæ* hexagonal masses of eggs are deposited in any convenient spot, numbering as many as seventy or even more, and the nymphæ differ markedly from the adults. Not having seen the metamorphosis of the "*Ochindundu*," I do not know if it be (like *R. personatus*) covered in its immature stages

with the viscid substance which causes particles of dust and small fibres to adhere not only to the body proper, but also to the legs and antennæ of the last-named insect, giving to it the weird appearance from whence has come its popular name of the Masked Bed-bug Hunter. The predaceous habits of the "*Ochindundu*" are to be expected, since other members of the family live on arthropods and even higher animals, including man. One species (*Prionidus cristatus*) feeds—both its nymphæ and imagines—upon all other insects it can capture, either in the larval or adult state, occasionally even overcoming and destroying its own kind. A powerful venom is injected into the victim when the strong proboscis is inserted, and it dies almost instantly. The bug then sucks the juices out of its prey and drops the empty skin (4).

Pathologic Importance.

The natives state that the "*Ochindundu*" regularly infests kraals and compounds for the sake of preying on ticks. This would seem to be reasonable, since many *Reduviidæ* are (as has been mentioned) predaceous, living on the ingested blood of hæmophagous arthropods, *e.g.*, *R. personatus* hunts the bed-bug (*Acanthia lectularia*). The "*Ochindundu*" thus may prove to be an unpaid assistant to the tropical sanitarian, helping him in the laudable task of combating the worst of all African vermin, which infests not only native lines, but is sometimes even found in white quarters. Another point which is worth mentioning is that the natives also state that the "*Ochindundu*" itself inflicts a bite which far exceeds in painfulness that of the tick upon which it feeds. I have seen several natives who claim to have been bitten by it. One of them was seen while he was still suffering from the effects of the bite. They compare its bite to that of a poisonous snake. These statements are borne out by what I can learn of the habits of other closely allied species. A variety of *R. personatus* is stated to cause intense pain by its bite, and it is said that when unskilfully handled it always bites. Its bite, like that of the "*Ochindundu*," is said to be almost equal to the bite of a snake, the swelling and irritation lasting for about a week. In some cases it has even proved fatal. Another species (*Conorhinus sanguisugus*), known in America as the Big Bed-bug, sucks human blood at first hand. Like the two insects just mentioned, *C. sanguisugus* inflicts a most painful wound, and its bite has been known to be followed by very serious results, the patient not recovering from the effects of it for nearly a year (5). It is very probable that "bites" attributed to scorpions, spiders, wasps, &c., are in some cases inflicted by the "*Ochindundu*" and its allies, of which latter I have collected three distinct species, which I hope to have determined as soon as opportunity offers. Three possible ways in which tropical *Reduviidæ* may attain pathologic importance occur to one:—

(1) By their destruction of disease-carrying creatures.

(2) By reason of their own venomous bites.

(3) Through their conceivable transmission of disease either directly by their own bites, or indirectly through other animals wounded and infected by them.

Supplementary Note on the "Ochindundu."

Just as I am posting the MS. of this paper I have received a letter from Mr. Austen, of the British Museum, who, writing under the date of November 3rd, 1905, assures me that my collections which I feared were lost have safely reached the Museum. It will now be possible to publish a determination of the bug above described by me, which I hope will appear in an early number of this Journal.

HORSE-FLIES (TABANIDÆ) AND DISEASE.

By Ernest E. Austen.

Zoological Department, British Museum (Natural History).

If we except the Simulidæ, which consist but of a single genus, numbering, so far as our present knowledge goes, considerably less than one hundred species, and the Hippoboscidæ, the few species of which are permanent parasites of mammals and birds, the horse-flies, or Tabanidæ, are the only family of Diptera in which the blood-sucking habit is, with a few possible exceptions, universal in the female sex. For, even among the mosquitoes, which will doubtless at once suggest themselves to the mind of every one who reads the previous sentence, there are many species—and, as the family *Culicidæ* is at present constituted, even some genera—of which the diet is all that the most ardent vegetarian could desire. But horse-flies possess yet other claims to attention. Not only are the Tabanidæ among the largest of all families of Diptera, already including as they do the enormous total of nearly sixteen hundred described species, but the flies themselves are of relatively large size. Lastly, like mosquitoes, horse-flies are practically ubiquitous. Although they probably did not contribute to the "infinite torment of flies" that added to the horrors of "The Defence of Lucknow," there are few spots on the earth's surface where horse-flies are absent; and from Alaska to Tierra del Fuego, from Siberia to Ceylon, Cape Agulhas, and the South Island of New Zealand, they force their unwelcome attentions on men and animals alike. In many parts of Africa they are especially abundant. The swarms of "serut-flies" (under which name are included several species of *Tabanus*) encountered on parts of the Upper Nile have made life burdensome to many a traveller, from the days of Sir Samuel Baker to the present time; and the many new species of *Hæmatopota* recently received from Angola and Uganda seem to show that the African continent must be regarded as the head-quarters of that bloodthirsty genus.

In view, therefore, of the interest now being excited by blood-sucking Diptera as actual or potential disseminators of pathogenic organisms, it may be

worth while to devote a few moments to a consideration of the evidence tending to incriminate the Tabanidæ. Truth to tell, horse-flies, though often regarded with suspicion, have not yet been conclusively proved to be the *regular* conveyers of any form of disease among domestic animals or man in any part of the world. It is important to distinguish between the "regular" conveyer of a disease-causing organism and a mere accidental carrier. In the case of malaria, sleeping sickness, tsetse-fly disease, and, almost certainly, yellow fever, each malady is conveyed by certain blood-sucking Diptera, and *in no other way*. But when the bacilli of a disease such as anthrax are carried on the mouth-parts of a blood-sucking fly, the insect is merely a fortuitous agent. That a Tabanid or other biting fly which has sucked the blood of an animal suffering from anthrax may convey the disease to a human being, or to another domestic animal, is quite possible. The author is informed by Lieutenant-Colonel C. T. Bingham (late I.S.C.), that in Burmah mahouts believe that anthrax, which is prevalent among elephants, is carried by Tabanidæ, and on one occasion Colonel Bingham observed Tabanidæ among a number of flies on an elephant which had died from anthrax. The evidence for and against the conveyance of anthrax by flies has been well summarised by Nuttall,[1] who, however, as the result of his researches, is "struck by the very few positive cases recorded of anthrax arising from the bites of flies."[2] Nuttall considers that it is probable that infection by this means is "the exception and not the rule."[3] In India, Rogers has succeeded experimentally in transmitting *surra* (a disease of horses, cattle, and camels, caused by the parasite *Trypanosoma evansi*, Steel, and closely akin to the African *nagana*, or tsetse-fly disease) by means of the bites of horse-flies, but the insects were used merely as inoculating needles, and transmission was direct.

In the South of France (littoral of Var à Cavalière), Louis Léger has recently met with a new flagellate parasite (described by him under the name *Herpetomonas subulata*) allied to *Trypanosoma*, in the alimentary canal of *Tabanus* (*T. glaucopis*, Mg., ♀) and *Hæmatopota*.[4] The writer in question states that the parasite is not common, and that he has met with it only four times in sixty specimens of the genera mentioned, collected in autumn on horses and cattle. It should be noted that species of *Herpetomonas* are parasitic not only in blood-sucking flies, but also in non-biting forms, such as *Musca*, *Sarcophaga*, *Pollenia*, and *Fucellia*; but, apart from the settling of flies on abraded surfaces or wounds, it is, of course, only blood-sucking forms that are capable of infecting vertebrates, should the parasites be found to pass part of their life-cycle in a warm-blooded animal.

In the French Sudan, according to Laveran,[5] who quotes L. Cazalbou,[6] the disease of dromedaries at Timbuctoo, known as *mbori*, and that termed *soumaya* or *souma*, at Ségou, which affects horses and humped cattle coming from Macina, both of which diseases are trypanosomiases, are propagated by *Tabanus ditæniatus*, Macq., and *T. biguttatus*, Wied., *var.* Professor Raphaël Blanchard has recently[7] given reasons for suspecting *Tabanus nemoralis*, Mg., and *T. nigritus*, Fabr., two South European species which are met with in North Africa, to be the disseminators of a trypanosomiasis which affects dromedaries in Algeria. Within the last few months it has been stated by Pécaud,[8] in a paper on a trypanosomiasis of the Middle Niger (which, he says, is undoubtedly the same malady as that of Cazalbou at Ségon, referred to above, and attacks horses, mules, donkeys, and cattle), that "the animals especially attacked are those living in the vicinity of the Niger or its affluents (*marigots*). There are no *Glossina* [tsetse-flies] in this region, and consequently Tabanidæ must be charged with propagating the disease." A bare statement such as this that tsetse-flies are absent from a district in which they might well be supposed to occur, falls very far short of scientific proof that the malady is disseminated by horse-flies. More than once in recent years have species of tsetse been shown to be abundant in localities in which they had previously been declared non-existent; and even should there be no tsetse on the Middle Niger, some other biting fly, such as *Stomoxys* or *Simulium*, may abound there. Still, it may be admitted that there is at least a case for enquiry. The part played by tsetse-flies in the dissemination of sleeping sickness, as well as nagana (tsetse-fly disease of animals), shows us that if horse-flies are capable of conveying organisms that are pathogenic to domestic animals, they may quite conceivably perform a similar *rôle* as regards human beings, and it is hoped that this little paper may have the effect of directing the attention of readers of this Journal to the question of "Tabanidæ and Disease."

THE ANATOMY OF THE BITING FLIES OF THE GENUS *STOMOXYS* AND *GLOSSINA*.

By Lieut.-Colonel G. M. Giles, I.M.S. (Retired.)

In the fifteenth report of the Liverpool School of Tropical Medicine, p. 14, published last year, the writer made some note of a trypanosomiasis of horses existing in Kumassi which appeared to be conveyed by a species of *Stomoxys*. Bodies which he regarded as an evolutionary stage of the parasite were found in the fluid taken from the stomach of a fresh insect dissected on the spot, but, unfortunately, the visit was

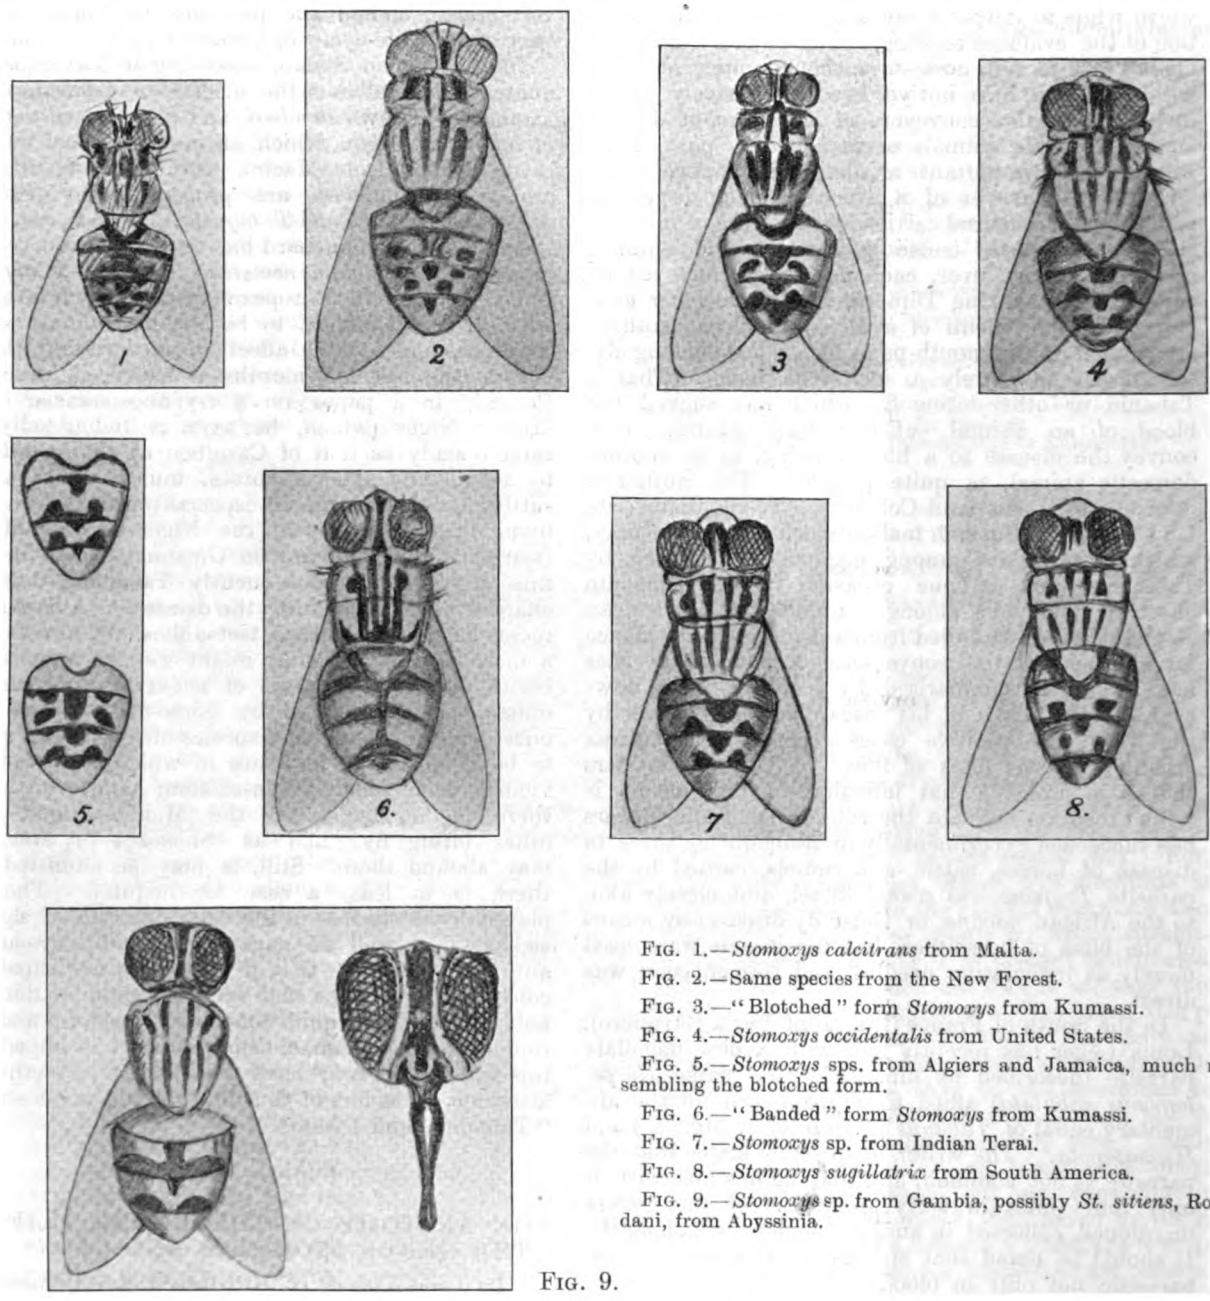

FIG. 1.—*Stomoxys calcitrans* from Malta.

FIG. 2.—Same species from the New Forest.

FIG. 3.—"Blotched" form *Stomoxys* from Kumassi.

FIG. 4.—*Stomoxys occidentalis* from United States.

FIG. 5.—*Stomoxys* sps. from Algiers and Jamaica, much resembling the blotched form.

FIG. 9.

so hurried, the object of our visit to the "Coast" being mainly to examine into the actualities and possibilities of anti-malarial sanitation, that little more could be done than to carefully prepare a number of the flies for subsequent microscopical examination.

The examination of this material has since been undertaken, but though bodies have been met with which it seemed might be referable to protozoal parasites, Prof. Minchin, to whom they have been submitted, does not consider that they represent stages of a trypanosome.

At an early stage of the work it became evident that some comparison with flies known to be free from disease of the sort was imperative, and it was necessary to turn aside and examine English specimens of the same genus which are, fortunately, fairly easily obtainable; and some comparison with the flies of the genus *Glossina* was clearly desirable. This piece of work took up much time, and as has been seen, remains the only solid result for the labour involved.

Meanwhile a report by Prof. Minchin on the anatomy of the tsetse-fly has appeared in the *Proceedings of the Royal Society*, V. B. 76, 1905, p. 531, and a similar paper on that of *Stomoxys*, by Lieut. F. Tulloch, R.A.M.C., is in the press. The present communication, therefore, is devoted mainly to such points as are not covered in these communications, which will be quoted whenever possible, though some repeti-

tion may be unavoidable. My thanks are greatly due to Prof. Minchin for giving me advance proofs of Lieut. Tulloch's valuable paper. It may be noted that the word "stomach" in Prof. Minchin's paper should, he wishes to state, read proventriculus. As a matter of fact, it is very difficult to avoid ambiguity in the use of terms such as "stomach," Strictly speaking, the diptera have no "stomach" in the sense of a localised dilatation of the upper part of the mid-gut.

In the mosquitoes, what is called the "stomach" is the entire mid-gut, with the exception of the narrow anterior part contained in the thorax and forepart of the abdomen. In the Muscidæ, including the species under consideration, there is no stomach in the sense of a localised dilatation, but the anterior part of the mid-gut forms a long tube of sausage form, and has distinguishable characteristics from the parts behind. Lowne, in his classical work on the blow-fly, calls this the "chyle stomach," and the continuation of the tube as far as the point of entry of the Malpighian tubes the "proximal intestine," while, between this and the commencement of the rectal valve is a short piece of intestine which he speaks of as the "metenteron," distal intestine, or hind gut. What Professor Minchin speaks of as the "sucking stomach" Lowne usually calls the crop, and as it is difficult to ascribe any aspiratory function to this organ the former term is to be preferred, although it is placed in the abdomen, and not in the neck, like the crop of a bird.

These explanations are necessary, as frequent references to Professor Minchin's account of the anatomy of *Glossina* are necessary to avoid needless repetition of work already performed, but Lowne's terminology will be adopted in the account that follows.

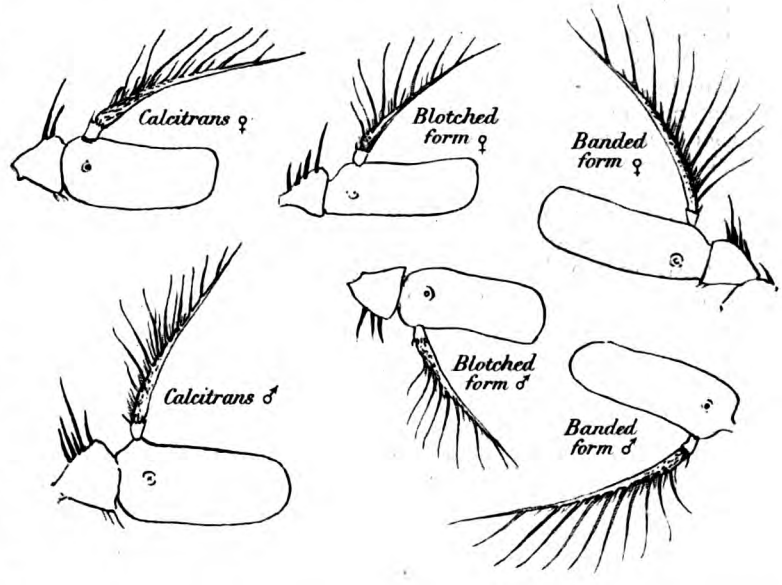
The genus *Stomoxys* includes a small group of biting flies, which resemble each other so closely that their distinction is an extremely difficult matter. It appears to be truly cosmopolitan, species or races being reported from all parts of the world. The type species may be taken as *Stomoxys calcitrans*, which is common in all parts of England, especially where horses are allowed to run wild, as in the New Forest, where it is locally known as the "forest horse-fly," and the pony owners have an erroneous idea that it is peculiar to the neighbourhood. It has been found also in Malta, North Africa, and Jamaica, and flies from the Indian Terai closely resemble it, as also does *St. enos* from New Zealand, and *St. vernon* from British Columbia. *St. occidentalis* from the United States, and *St. suggillatrix* from South America, are also closely similar.

Curiously enough the flies brought by me from Kumassi, and collected together from a swarm that was tormenting the animals in the horse lines there, included two fairly distinguishable forms.

As Mr. Austen, of the British Museum, is shortly undertaking an examination of this genus, and careful drawings are being prepared for the purpose, it was decided not to attempt to name these forms, but to speak of them for the present as the "blotched," and "banded" forms respectively. The former closely resembles *C. calcitrans*, while the latter is much like some specimens in the Museum derived from the island of Mauritius.

The accompanying rough figures give some idea of the markings of these various forms and of the closeness of their resemblance to each other, but does not pretend to close accuracy or proportional size, as any attempt to do so is clearly superfluous in view of the fact that the task is at present in the skilful hands of Signor Terzi.

I am inclined to think, however, that a means of distinction is to be found in the flagellum of the antenna or arista, as it is usually called by dipterologists. This structure is provided with a discrete fringe of long hairs, and I find that the number of these varies in the different forms, as well as sometimes in the sexes of the same species. Besides the long hairs, there are a number of shorter ones which may be spoken of as accessory hairs, and in *Stomoxys calcitrans* these are much longer than in either the "blotched" or "banded" forms.



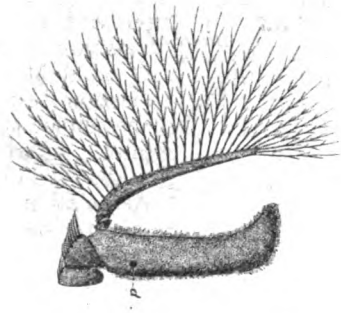
The above figures will illustrate my meaning better than much description.

The long main hairs spring more from the dorsal side of the arista, as it is usually carried by the insect, and so project almost directly upwards, while the accessory hairs are arranged along its inner side, and project inwards and upwards. In specimens mounted in balsam both ranks are forced more or less into the same plane, and are so represented in the figures. Besides the two principal ranks the proximal half or more of the arista is closely clothed with hairs, which in some cases are as long as those I have termed the accessory hairs, but neither these nor the extremely close dress of fine hairs that cover the antenna proper are represented in the camera

lucida drawings. The principal hairs are, it will be noted, simple.

A glance at the drawings shows that the three forms can be quite easily distinguished, and moreover, that the "banded" Kumassi *Stomoxys* resembles the English *St. calcitrans* more than the "blotched" form, which resembles the latter more closely in colouration. Both sexes in the "banded" insect have ten principal hairs, whereas in the blotched one there are but eight in each sex, and the entire arista is shorter proportionally to the last joint of the antenna. In both sexes on each of these forms the accessory hairs are quite short. *Stomoxys calcitrans* has seven principal hairs in the ♀ and nine in the ♂, and may be further distinguished from the banded form by the comparative smallness of the fork formed between the termination of the arista and the most distal principal hair. The accessory hairs are also very much longer than in either of the other forms, especially in the male, a further peculiarity of which is that the next but longest principal hair is provided with a small branch about half-way in its length. As far as observed these characters appear to be constant, but the series examined is not numerous enough to speak with certainty on this point. The remaining forms mentioned have not been examined, as they were British Museum specimens, and it is hardly possible to produce an accurate drawing for comparison without mutilating the specimen so as to be able to mount the antenna in balsam.

The antenna of *Glossina*, a drawing of which is reproduced from Mr. Austen's monograph, as will be seen, differs entirely in having compound principal hairs. Among the flies recently sent to the Museum is a *Stomoxys* from the Gambia, easily distinguishable by the brilliant white marking of the frons, and which answers fairly to the description of *St. sitiens* from Abyssinia.

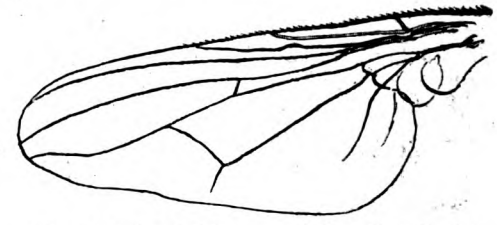


Rondani's description is, however, too brief to admit of certain identification without comparison with his types. Besides this there is a form from Somaliland which much resembles my "banded form," in marking, and as far as can be made out in the armature of the arista, but is easily distinguished by the pinkish colour of the lighter markings on the frons. On the whole, however, it seems improbable that more than half-a-dozen forms will require to be distinguished.

The genus *Stomoxys* was founded in 1762 by Geoffroy "L'Hist. abregeé des Insectes," ii., p. 538), with the following definition: "*Antennæ patellatæ seta laterali pilosa, os rostro sululato simplici acuto, ocelli tres.*" He notes further its close superficial resemblance to the common fly, but remarks that "its more widely separated wings and its shorter abdomen give it a look that make it easily recognisable to close observation. In France it is commonest in autumn, and he points out that this probably is the origin of the old French saying, "les mouches d'automne pignoient." His figure is unmistakable.

A more modern definition is to be found in Schiner's "Fauna Austriaca," i., p. 577, but is no better suited to the requirements of modern classification, as it is so planned as to include *Hæmatobia*, which differs from *Stomoxys* in the easily recognisable character of having the palpi nearly as long as the proboscis, whereas in *Stomoxys* they are of quite insignificant dimensions.

The venation of the wing presents nothing very characteristic, and is so closely similar in the various forms that it is unlikely to be of much service for the distinction of species. Moreover, owing to the wing being far from flat it is difficult to so mount specimens as to obtain strictly comparable outlines for comparison.



Stomoxys, banded form, ♂. Venation of wing.

Just as in the case of the common house-fly, the tropical forms on *Stomoxys* are considerably smaller than the English insect. The two sexes resemble each other so closely that it is difficult without close examination to distinguish them from each other, especially as both males and females are equally bloodthirsty, and a gorged male often distends its abdomen to such an extent as to look much like a gravid female. The most prominent point of difference is that the space between the eyes is much wider in the females. Examined casually the abdomen differs but little in the two sexes, but a closer examination reveals the point that while that of the female ends in a papilla-like ovipositor, the hypopygium of the male is tucked under him in much the same way as that of the female crab. On closer examination the male genital apparatus proves to be of a very complicated character, and this, too, may prove of service in classification.

HYPNOTIC SUSCEPTIBILITY OF THE NEGRO RACE.

By C. W. Branch, M.B., C.M.Edin.
St. Vincent, B.W.I.

There being, as I believe, but little so far recorded of therapeutic hypnotism in negroes, the included figures may be of interest to those practising in

THOMAS EDMONSTON CHARLES, M.D., LL.D.Edin., F.R.C.P.Lond.

tropical climates, who will take the trouble to verify the utility of hypnotism.

I do not propose to give any results of therapeutic suggestion, but merely to indicate the psychological fact of the degree of susceptibility of the black race to hypnotism.

For the purpose of obtaining a percentage, notes were kept of a 100 consecutive persons of pure negro blood who were tried under various conditions favourable or otherwise to hypnotism. Of these it was found that 87 were influenced at the first sitting. Of the 13 who failed, two whom it was desirable to hypnotise were influenced at the second try. The other 11 were not tried again. Of these last one was a case of mania, one a child of feeble intelligence, and two very aged doting persons. All these four were not subjects who could be expected to be influenced.

The method employed was almost invariably simple persuasion to sleep, aided usually by stroking of the forehead, or, in a few cases, by fixation of the eyes by the finger or other object.

In two cases of mania fascination was resorted to, and failed with one. Passes were tried without success on the two cases of mania and on the imbecile child. In some instances persuasion addressed to several persons at once and indirect persuasion (of another person) have been used. The latter was unsuccessful on one occasion only, and that was with one of the dotards.

Unintentional hypnotism has occurred more than once, though none of those so influenced are included among the 100 cases.

Compared with the results among whites in Europe, where 80 to 84 per cent. are found susceptible after many tries, these figures show that the negro is distinctly more susceptible. It might be inferred that a more expert hypnotist would find the negroes susceptible to the extent of nearly 100 per cent.

So easily influenced do I find my black and coloured patients that at hypnotic cliniques all the patients in the room were hypnotised simultaneously. Those who had previously attended fell asleep at the bare command, while new cases, by imitation and persuasion, were asleep in a minute or less. In this way ten persons have been operated upon at once, and there is probably no limit except that of accommodation.

It is probable, that given the attitude of expectancy, such as that of persons desiring medical treatment, a Liebault or Bernheim could hypnotise to sleep as many blacks as could hear and understand him, as readily as an expert prestidigitator hypnotises his entire audience into visual illusions and sometimes hallucinations.

The ages and sexes of the 100 cases referred to are shown in the table below:—

Age	Hypnotised M.	Hypnotised F.	Not Influenced M.	Not Influenced F.
3 to 14 years	7	7	0	1

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 „ „ 6/-;
200 „ „ 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 „ „ „ 11/-;
200 „ „ „ 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

APRIL 2, 1906.

A TROPICAL MEDICAL ASSOCIATION.

HAS the time arrived when it is possible to found an association of medical men interested not only in Tropical Medicine, but in the position Tropical Medicine as a definite branch of General Medicine should take and aspire to? The question has been brought keenly home to me by the difficulty encountered on several occasions of obtaining permission to hold a Section of Tropical Diseases at the annual meetings of the British Medical Association. The Section of Tropical Diseases has on several occasions been omitted by the authorities to whom the allocations of sections at the annual meetings of the Association have been entrusted, and it was only by representation and persuasion that a tardy acquiescence to hold the sectional meeting was obtained.

This year, again, at the meeting at Toronto, a Section of Tropical Diseases is omitted; and although the writer has represented the matter both to Canadian authorities and to the Council of the parent Association, nothing has come of it.

The reply on several occasions has been that Tropical Diseases might be considered under the auspices of or as a sub-section of the "Medicine" Section. Any one acquainted with the impossibility of dealing with all the papers sent to the Section of Tropical Diseases at the annual meetings, is aware that to include

Tropical Diseases in any other section or sections is calculated to prevent men interested in Tropical Diseases attending the meetings. Not only is it that there is no time for the papers to be read, but when a subject appertaining to tropical diseases is brought forward, the medical man who reads the paper or opens the discussion wishes to have the matter laid before experts, and before those interested directly in the disease or investigation he has undertaken. The Section of Tropical Diseases in connection with the annual meetings of the British Medical Association has been a pronounced success. The numbers attending the Section, even remembering the scattered constituency from which it is gathered, have frequently been larger than any other section of the annual meeting; and the importance and scientific value of the communications may surely, without prejudice or exaggeration, be stated to be of superlative importance.

From yet another point of view are the practitioners in the Tropics deserving of full recognition at the annual meetings. The number of medical men directly interested in Tropical Medicine amounts to some 6,000, and they form the largest section of qualified medical practitioners on the British Register whose interest is centred in any single subject. Of the 34,000 men on the register, some are interested in general medicine, some in surgery, others in gynæcology, obstetrics, skin, eye, throat, ear, nose, epidemiology, anatomy, physiology, pathology, nervous diseases, ambulance work, dentistry, or other sections provided at the annual meeting; but no single section can show so large a body of men on the British Register to whom one single section presents so singular an adhesion as that of Tropical Diseases.

The writer is led to believe that in expressing the above opinions, he is merely voicing those of most of the members of the large body of British practitioners interested in Tropical Medicine, for the need of some metropolitan rallying point for our numerous but scattered body is sufficiently obvious. Assuming such a society to be formed, it would of course be well to seek affiliation with the British Medical Association, as such a step would enable the association to make their voices heard in the councils of the parent society.

The writer desires, before proceeding further in the matter, to have the opinion of medical men to whom this question is one of importance. Many subjects of supreme consequence to the State and to the individual would be dealt with by such an association, and in time it ought to become one of the most important of the several departments of medicine, both scientifically and ethically.

The readers of this Journal who wish their names to appear on the General Committee of "A Tropical Medical Association," should send in their names, addressed to the writer at the office of this Journal, 89, Great Titchfield Street, Oxford Street, London, W. It is to be distinctly understood that the contemplated association is not a separate association, independent of the British Medical Association, but one intended to promote the interests of Tropical Medicine within the parent Association, and constituted so that the wishes of medical practitioners in the Tropics may be authoritatively and collectively expressed.

JAMES CANTLIE.

ANTI-MALARIAL SANITATION IN INDIA.

THE short "Editorial" which we reproduce below from the columns of the Indian *Pioneer* is a gratifying proof of progress in the education of public opinion in India on the subject of the possibilities of anti-malarial sanitation.

The facts, indeed, as therein quoted from Major Duke's report, are of a kind to convert the most sceptical, and we congratulate our influential lay contemporary on its altered attitude with respect to the question; for it is not so long ago that the *Pioneer* and the army of "common-sense" correspondents whose letters found a favourite home in its columns, found it hard to sufficiently express their contempt for those who believed it possible to sufficiently diminish the number of mosquitoes to effect a corresponding diminution in the sick list of malaria. The measures adopted by Major Duke, it will be noted, are in no way novel, but are simply those that have been recommended from the first by Major Ross and those who have associated themselves with him in the campaign. Now that the *Pioneer* has been converted, we may perhaps hope that the Indian Government may follow suit, and that perhaps in ten or twelve years or so we may hear of its undertaking general adequate measures for the protection of our troops in cantonments and of the civil population of our great Indian towns.

"The report of the Medical Officer in Baluchistan for the year 1904, though late in issue, contains at least one fact that is worth recording. In Baluchistan, malaria is 'at once the greatest primary cause of illness, and indirectly gives rise to a large proportion of the ill-health expressed in other terms.' To show what can be done by preventive measures Major Duke quotes the records of the Shahrig Railway Hospital, which is largely attended by the civil population of the tahsil and bazaar and villages near. The average annual number of malarial cases treated between 1898 and 1900 was 2,827, and in 1900 there were 3,227 cases. The following year the number rose to 3,376 cases, and in 1902 special anti-malarial measures were enforced. Quinine was distributed, surface drainage and the kerosining of pools were adopted, and the malarial cases fell to 2,722. In 1903 these measures were continued, and in addition, the cultivation of rice within a mile of the tahsil was prohibited, and in that year the cases fell to 1,792. In 1904, with the continuance of these measures, there was a further fall to 957 cases. At the same time, in the dispensaries above and below Shahrig, in the last-named year, there was in the one case a steady and in the other a great increase in malarial cases. Thus 1904 was evidently not a healthy year in the district, and there is no evidence of any exodus of population. The effectiveness of the anti-malarial campaign is thus clearly established."

Translation.

PRELIMINARY STATEMENT ON THE RESULTS OF A VOYAGE OF INVESTIGATION TO EAST AFRICA.

By R. KOCH.

(*Translated from the German by P. Falcke.*)

(*Continued from page* 76.)

(4) TSETSE-FLIES AND TRYPANOSOMA.

I HAVE met with four different species of the genus *Glossina* during my expeditions. These are *Glossina fusca*, *G. morsitans*, *G. pallidipes* and *G. tachinoides*.

In addition, *G. palpalis* has been found in the islands of Victoria Nyanza belonging to German territory by Dr. Feldmann, and probably also *G. longipennis*, which I caught during my journey by the Uganda Railway between Voi and Tsavo Stations, not far from the German frontier. Thus six out of the eight species of *Glossina* hitherto described occur in the German East Africa.

It has hitherto been taken for granted that *G. morsitans* is the carrier of tsetse disease. This species, however, is only found in certain tracts of the Protectorate, particularly in the north and south, between the great lakes; in the middle, its place is filled by *G. pallidipes*.

G. tachinoides, the smallest of the *Glossina*, appears to be widely distributed, but only appears in small numbers. On the other hand, I have encountered *G. fusca* in great numbers wherever tsetse disease is prevalent.

I was first successful in discovering specimens of *G. fusca* infected with trypanosomata, and in the following manner. On examining the flies under the microscope I noticed that the proboscis was always filled with a liquid which, by pressure on the bulb of the proboscis, could be squeezed out in the form of a clear droplet. As it might be presumed that the fly, in puncturing, injects this droplet under the skin of its victim, and that infected flies must have trypanosomes in this liquid, I examined the drops exuded from a number of specimens microscopically, and actually found numbers of trypanosomes in a few cases. The circumstance that the liquid was quite devoid of red blood cells, that the trypanosomes were much more numerous than they ever are in the blood, and that they exhibited various stages of development, led one at once to the conclusion that these flies do not transmit the disease direct by injecting the blood of a sick animal into a healthy one; but that conditions here are similar to those that exist in malaria parasites, *i.e.*, that the trypanosomata undergo a stage of development in *Glossina*. The correctness of this assumption was fully verified when the flies, whose probosci contained trypanosomes, were more minutely examined. Sections of the stomach, even when quite devoid of blood, contained large numbers of trypanosomes in different stages of development. They are either entirely absent from the intestine, or are only present in very small numbers. I have never been able to definitely establish the presence of trypanosomes in either the glandular organs, the Malpighian tubes or elsewhere than in the situations mentioned.

In all nearly sixty flies containing trypanosomes were examined, including one specimen each of *G. morsitans* and *G. pallidipes*.

It appears to me, therefore, a foregone conclusion that in German East Africa the tsetse disease is transmitted not only by *G. morsitans*, but also by *G. pallidipes*, and particularly by *G. fusca*, which quite coincides with my observations on the distribution of these species.

As far as I have made out, the cycle of development of the trypanosome in the *Glossina* is as follows: The trypanosomes ingested with the blood, the number of which, under natural conditions, is very limited, soon multiply in the stomach by longitudinal division, and also increase in size. The degree of growth will be best seen by a comparison between fig. 15, which represents a trypanosome from the blood of an ox, and fig. 16, which shows a trypanosome from the stomach of an infected *Glossina*. Simultaneously a remarkable differentiation sets in.

Part of the large trypanosomes become thick and plump, with a rich blue-staining plasma, and exhibit a rather large, rounded chromatin body of loose consistency (fig. 16). Other portions of the parasites are exceedingly slender, and their plasma does not take the blue stain, but possess a long, thin, dense chromatin body (fig. 17). Sometimes one type predominates, sometimes the other, and in different parts of the same preparation close aggregations of each form may be met with.

(*To be continued.*)

Abstract.

THE PREVENTIVE TREATMENT OF DISEASES (Les Médications Préventives). By Dr. L. Nattan-Larrier. 1 vol. in 16. Baillière et Fils, Paris.

The history of preventive medicine commences with inoculation for small-pox and vaccination, but in 1880 the work of Pasteur and of Toussaint opened up a new field of research by demonstrating that the inoculation of a modified microbic culture might confer a specific immunity on animals. The principle of preventive bacterio-therapeutics has been definitely established since 1881. In 1885 Ferran published the good results which he had obtained by treating cases of Asiatic cholera by means of a vaccine derived from cultures of the comma bacillus; and although his statements were at first treated with much scepticism, they would appear to have been since confirmed by Haffkine's researches. The remarkable discoveries of Behring and Kitasato in 1890 of the antitoxic sera resulted in the serotherapeusis and seroprophylaxis of diphtheria and of tetanus. Since then the question has advanced with giant strides, and (as will be shown in this book) it is now possible by means of injections of serum or of modified cultures to arrest the development of diphtheria, plague, cholera, enteric fever, tetanus, and possibly also puerperal fever. Immunisation by serum is a *passive immunity*, whilst immunisation by modified cultures is an *active immunity*.

[For want of space I shall limit my remarks to those on Plague, Cholera, Enteric Fever, and Yellow Fever, as they apply more especially to warm climates. —J. E. N.]

PLAGUE.

Two specific methods have been proposed and employed to combat plague: one of these we owe to Yersin, namely, immunisation by anti-plague serum; the other, due to Haffkine, consists in the inoculation of cultures killed by heat. We will now consider each of these two methods.

I. *Preventive Serotherapeusis of Plague.* — The earliest researches of Yersin, Borrel, and Calmette

demonstrated the immunising power of the anti-plague serum. In January, 1897, Roux was able to state in the *Académie de Médicine*: "Hitherto the serum has only been tried in the case of confirmed disease. According to what has been observed in animals, it ought to be still more efficacious in the prevention of plague than in its cure. It would therefore appear necessary, when a case of plague has suddenly appeared in a house, for all persons who are exposed to contagion to be injected with serum as a preventive measure. Yersin thinks this is an efficacious measure against the diffusion of the disease." Cases of preventive serotherapeusis soon became numerous, the dose of the serum usually amounting to 10 cc., which, however, appeared to confer immunity for only fourteen days. It is therefore necessary to renew the preventive injection every twelve days in the case of individuals who remain in the epidemic focus; this necessity is the more imperative, as, although the morbidity is lessened, the mortality remains as high in the case of individuals whose immunity is exhausted as it is amongst those who never underwent any preventive injection. In consequence of the short duration of the immunity conferred by the serum, and of the need for the revaccination to be repeated several times a month, Simond and Yersin were of opinion that "sero-vaccination was not applicable in practice for an entire population, although an excellent method to be adopted in individual cases or in families."

II. *Inoculations by Sterilised Cultures.*—Haffkine's method seems on the whole to answer best for an extensive prophylaxis of plague, as it can be applied to a whole population; it has been largely used in India with the sanction of Government. The *rationale* consists in cultivating the *Bacillus pestis* in bouillon, under a layer of butter for a month, and then enclosing the culture in tubes, which are now sealed and heated for an hour at 72° C.; the culture enclosed in these tubes is then ready for inoculation purposes. The duration of the immunity conferred by injection varies from four to six months, and, in any, case, does not extend to the year, although Haffkine has noted some cases where it would appear to have been prolonged even up to two years; however, the general opinion in India is that immunity may be considered as exhausted at the end of three months, and therefore those individuals who reside in plague-stricken regions renew their inoculation every three months.

The French opinion, held by Calmette, Salimbeni, and Yersin, is that immunisation only commences by slow degrees, after a period in which vaccination favours the action of the plague bacillus. The British opinion is notably different, for it maintains that the period which elapses before the acquisition of immunity does not exceed twenty-four hours. The injection is somewhat painful, and although followed by general lassitude, frontal headache, a marked rise of temperature, &c., for a period varying from twelve to forty-eight hours, is not accompanied by serious results. The febrile reaction is the greatest objection raised against inoculation, and seriously militates against the wholesale vaccination of the population with Haffkine's plague-prophylactic fluid. The dose should not be less than 5 cc., and the operation is usually repeated in two or three weeks' time.

Conclusions arrived at.—Both methods of preventive treatment are efficacious.

The serotherapeusis, although more rapid and more certain in its action, only confers a transitory immunity, and therefore can only protect the individual from contagion by repeated inoculations, which is a difficult matter when one has to deal with the whole of the population; on the other hand, it is an excellent method for individual prophylaxis, such as in the case of the medical *personnel*, the employees of the sanitary services, or the families of the patients. Sero-vaccination, when combined with isolation and disinfection, holds high rank among the methods of defence against plague.

Major M. B. Bannerman ended his report in 1902 on the application of Haffkine's method with the following remarks: "The inoculation is absolutely innocuous: inoculations made during the period of incubation of plague in many cases exercise an abortive action on the disease. Inoculation confers immunity to a high degree; and if, in spite of the inoculation, an individual is attacked by plague, his chances of recovery are much greater."

Haffkine's method probably still requires to be perfected, but it already answers to a great extent to the desiderata of a preventive treatment applicable to a large number of individuals when an entire country is threatened with an invasion of an epidemic of plague.

Cholera.

In 1885 Ferran announced his method of vaccination against cholera, which reduced the mortality by exactly one-half. Since 1894 Haffkine's method has given even more remarkable results, although no official pressure was used, and only those individuals were vaccinated who freely consented to undergo this treatment. Haffkine's method consists of a double inoculation with an interval of five to eight days; the *first* injection at first consisted of cultures of the comma bacillus sterilised by the addition of carbolic acid, but this method has been replaced by the use of living cultures attenuated by heating up to 72° C.; the *second* injection is a culture of high and constant virulence obtained by a continuous series of "passages" of the bacillus through the peritoneum of guinea-pigs, the comma bacillus thus acquiring a virulence which is twenty times stronger than before. Immunity is exhausted after one year.

The symptoms of anti-choleraic vaccination consist in a localised œdema at the seat of injection, which is painful to the touch, accompanied a short rise of temperature, but no serious accident has ever been caused thereby. Wherever cholera has been sufficiently scattered and prevalent so as to lead one to suppose that the whole of the population has been equally exposed to infection, and wherever the mortality has been high, in every instance this mortality has been greatly reduced in the case of the inoculated. A preventive anti-choleraic serum has also been tried, but it has hitherto proved less useful than the vaccine in those regions in which cholera is endemic, but the question is not yet definitely settled.

Enteric Fever.

I. *Serotherapy.*—Although the anti-typhoid serum of Professor Chantemesse possesses undeniable pre-

ventive properties, it has rarely been employed prophylactically, so we cannot yet ascertain to what extent preventive serotherapy will enter into practice.

II. *Wright's Vaccine.*—The vaccine employed by Wright to obtain immunity against typhoid fever is somewhat allied to Haffkine's vaccines; both consist of cultures sterilised by heat, but whilst the microbes are inoculated by Haffkine, Wright decants his cultures and only injects their toxins. The process of the preparation of the vaccine may be summed up thus: Culture of Eberth's bacillus for a fortnight in the drying-stove at 37° C., sterilisation at 65°, addition of one-half per cent. of lysol. The filtered liquid is used for inoculation; its degree of virulence is such that the inoculation of 5 cc. entails in twenty-four hours the death of a guinea-pig weighing 250 grammes.

The dose varies from $\frac{1}{2}$ to $\frac{3}{4}$ cc., this latter being the dose most suitable when an interval of several weeks must elapse between inoculation and exposure to infection, and when one cannot resort to inoculations in succession. On the other hand, when inoculation is practised in the very midst of the epidemic a weaker dose must be employed, and after an interval of one week a second injection must be given, but in a stronger dose. The inoculation may be given in the hypochondrium, or any other part where there is an abundance of loose connective tissue. The injection of a medium dose does not usually give rise to any well-marked symptoms, and the patient ought to return to duty in three days. When too strong a dose has been injected the general symptoms become more severe, but without causing immediate danger.

Immunity is produced more or less rapidly, according to the dose of vaccine employed; when a very feeble one has been given, immunisation may be produced in about twenty-five hours; for this reason, in epidemic centres a feeble dose should first be given, and this should be followed by a second one. The duration of immunity conferred by Wright's vaccine does not exceed one year, and may begin to decrease after six months.

Conclusions.—Wright's method, without entailing any danger for the inoculated individuals, seems to give very favourable results, viz., considerable diminution in the number of cases, and relative mildness of the enteric fever which may develop, in spite of the injection. The inoculation may be dangerous if the person is inoculated with too strong a dose whilst he is in the fever zone when the epidemic is at its height, as he is then more likely to contract the disease. Wright's vaccine is especially indicated in the case of troops employed in Colonial expeditions.

Yellow Fever.

The researches of Marchoux, Salimbeni and Simond, if still far from solving the question of preventive serotherapy and in yellow fever, nevertheless bring some important contributions to this question, as they have carefully ascertained the period during which the patient's serum contains the organism of the disease, and have sought to discover to what degree the blood of yellow fever patients might contain immunising substances. These researches on the preventive serotherapeusis of yellow fever were undertaken (*a*) by means of virulent blood, sterilised in various ways; (*b*) by means of serum from convalescents, this serum no longer containing the agent of yellow fever, but being endowed with immunising properties.

(*a*) On the third day of the disease the blood of the yellow fever patient contains the pathogenic agent, an invisible microbe, capable of provoking yellow fever; the inoculation of $\frac{1}{10}$ cc. of serum is sufficient at this period to give yellow fever; but if heated up to 55° C., this serum becomes harmless, but still preserves its immunising properties.

(*b*) After the fourth day the blood of the patient is incapable of transmitting the disease; it was therefore thought that this sudden disappearance was accompanied by the presence of immunising bodies in the serum. The injection of serum from a convalescent patient may indeed confer immunity on a healthy subject; but this serum only retains this property during a period of twenty-six days, after which it can only confer partial immunity. However, these admirable results cannot as yet be considered as entirely confirmed, and their prophylactic measures, although of the highest importance, must still be considered as in the experimental stage only. J. E. Nicholson.

EXTRACTS FROM COLONEL GORGAS' MONTHLY REPORTS FROM THE CANAL ZONE, PANAMA.

By Isaac Brewer, M.D.

Trypanosoma in Rats on the Isthmus of Panama.

During the month of November, 1905, Dr. Arthur I. Kendall, Acting Chief of the Board of Health Laboratory of the Canal Zone, examined 1,563 rats, and found 278 infected with *Trypanosoma lewisi*.

During the same period he examined 547 mice, in 39 of which he found trypanosomes.

Malarial Parasites.

According to the monthly reports issued by Colonel Wm. C. Gorgas, Chief Sanitary Officer of the Isthmian Canal Commission, 1,942 blood examinations were made from September 1st to December 31st, 1905.

Malarial parasites were observed as follows:—

Single tertian	772
Double tertian	17
Æstivo-autumnal	764
Quartan	4
Mixed infections	78

Parasites in Fæces.

The following results of 394 examinations of stools made by the Sanitary Department of the Isthmian Canal Commission during September, October, and December, 1905, are tabulated from the monthly reports issued by Colonel Wm. C. Gorgas, Chief Sanitary Officer of the Canal Zone:—

Ova of *Uncinaria duodenale*	101
Ova of *Tricocephalus dispar*	104
Ova of *Ascaris lumbricoides*	58
Amœba dysenteriæ	30
Rhabdonema strongyloides	21
Cercomonas intestinalis...	19
Balantidium coli...	2
Myiasis	2
Trichina spiralis	1
Bacillus dysenteriæ	9
Negative	116

In 2,512 analyses of urine during the same period hæmoglobinuria was observed 13 times.

Review.

BLOOD-SUCKING FLIES AND HOW TO COLLECT THEM. By E. E. Austen.

The British Museum have issued a second edition of this valuable pamphlet, which should be in the hands of every tropical practitioner.

Although in the main a reprint, a description of the *Leptidæ* has been added, as this family occasionally exhibits bloodthirsty habits. We should have liked, however, a figure of one of the alleged blood-sucking species, so as to know them when we see them.

Other notes, for example, on the Implication of Stomoxys in the transmission of Surra, have been added, which show how careful Mr. Austen is to keep the pamphlet up to date.

A further addition is a note by Lieut.-Col. Giles on the preservation of insects intended for histological examination.

The pamphlet is published at the nominal price of 3d., and Mr. Terzi's beautifully drawn and accurate figures are alone worth a great deal more than the small outlay; and the additions, though not extensive, are sufficient to make the acquisition of the new edition desirable.

We were somewhat surprised, therefore, when a copy of the old edition was tendered us on demanding one at the Catalogue counter of the Museum. We trust this was due to delay in furnishing the salesman, and not to a desire to "work off" the old stock. Such a petty economy would be much to be deprecated, as it might, for example, easily result in the museum losing specimens of the *Leptidæ* owing to the attention of collectors not being drawn to them.

Correspondence.

To the Editor of the JOURNAL OF TROPICAL MEDICINE.

DEAR SIR,—In a recent copy of the Journal Dr. Wellman referred, in his "Notes from Angola," to the treatment of so-called "malarial ulcers" by local applications of quinine.

May one enquire how the application is made? Is it the emulsion in cod liver oil that is used (see *Lancet* of 1902), or is there some fresh method of application?

Yours, &c.,
W. D. G.

Drugs and Remedies.

CYPROL—a distillation of Cypress oil—is commended as an excellent remedy in Whooping Cough. F. A. Rogers, 327, Oxford Street, London, supplies the pure concentrated oil—Cyprol, as well as an essence, a liniment, and pastilles prepared from the oil.

GASTRODYNIC—a compound enzyme palatinoid—a combination of Pancreatin Pepsin and Lactophosphate of Lime, prepared by Messrs. Oppenheimer, Son and Co., Limited, London, seems an effective remedy in dyspepsia. The ingredients are in equal quantities of one grain in each palatinoid, and one to three palatinoids may be given after meals in cases of ordinary dyspepsia.

XAXA—an acetyl-salicylic acid, issued by Messrs. Burroughs Wellcome and Co. in five-grain tabloids—appears to possess the therapeutic properties of salicylic acid and its salts without unpleasant after-effects.

For the relief of pain fifteen grains of "Xaxa" may be given at a single dose, with ten-grain doses repeated in one hour until three or four doses have been given.

Books and Papers Received.

WE have received "The Doctor's Handy Reference List" from Messrs. Pulman and Sons, 24-26, Thayer Street, Manchester Square, London. This is a useful compendium, and affords exact information concerning asylums, sanatoria, convalescent homes, nursing homes, &c.

Notes and News.

PLAGUE has broken out in Seistan, in Eastern Persia, the frontier province of that country towards India. The nature of the disease has been confirmed by bacteriological information, but it is said that the disease is not spreading. Captain Kelly, I.M.S., has been specially sent from Quetta to render assistance.

A splendid example of the warm affection that grows up between the people of India and their European medical officers is afforded by the munificent donation of 10,000 rupees (£670) which has been received by the Central Committee of the Countess of Dufferin's Fund from Brig.-Surg. J. Law, Indian Medical Service (retired). The interest on this sum, in accordance with the donor's desire, will be annually expended in the Central Provinces where he spent the greater portion of his service. Retired Indian medical officers are seldom too well off, especially if they have passed most of their time in the Central Provinces, which is one of the least prosperous parts of our Indian Empire. In point of fact, the proceeds of the private practice of the men stationed there are much on a par with Mr. Bob Sawyer's, which readers of "Pickwick" may remember might be "put into a wineglass and covered over with a gooseberry leaf." Viewed in comparison with the colossal donations to charity of financial magnates, the sum may not appear large to European eyes, but it probably represents far greater personal sacrifice. With such warm feelings existing between doctors and their Indian patients it is hardly wonderful that the native chiefs and wealthy civilians should view with strong resentment the petty-minded restrictions on private practice inflicted on the Service by the late Viceroy, Lord Curzon. As an old Sikh Sirdar remarked the other day anent this question: "It is very hard that a man should not be allowed to do what he likes with his own." There is no more libellous assertion than that the Indian is lacking in the virtue of gratitude, for their folk-lore and epic literature conclusively show that a generous recognition of benefits received is regarded by them as the first requisite of the heroic character.

"Unification."

A correspondent of the *British Medical Journal* of March 17th (S. G.) makes a number of thoroughly practical suggestions on the organisation of our Imperial medical services. While regarding "Scalpel's" remarks on "Surgery in the R.A.M.C.," in the same journal for December 25th, as quite uncalled for, there can be no disputiug the assertion that efficiency, whether in surgery or hygiene, is largely a matter of practice, and that during peace time the work of the military surgeon is rather that of sanitary specialist than of an operative surgeon. Hence, could it be arranged, the plan of combining our military and colonial medical services, as advocated by "S. G.," could hardly fail to promote efficiency in each service, and would probably be popular with the best officers of both.

S. G. writes as follows:—

"Surgery in the R.A.M.C.

"I have read 'Scalpel's' remarks on surgery in the R.A.M.C. in the *British Medical Journal* of December 23rd, 1905, p. 1682. There is no doubt that lack of opportunity is the great bar to efficiency in surgery among men of the R.A.M.C. As a remedy I would propose a dual medical service, one for India and one for home and the Colonies. I think the present dual service for India a mistake. I would do away with the R.A.M.C. there and make the I.M.S., increased in strength, responsible for the care of the army, British and native. The smaller civil surgeries and dispensaries I would hand over to assistant surgeons and hospital assistants. Here we would have a magnificent reserve for this class, sufficiently strong in numbers and thoroughly trained in professional work. In like manner I would make college appointments and the care of the large civil surgeries, the charges of gaols, &c., prizes for the officers. Here, again, we would have a magnificent reserve, capable of taking the field, fresh from the charge of hospital where as much surgery is done as in most of the large London hospitals. At present a young officer of the R.A.M.C. comes to India where everything is new to him. Tropical diseases present phases and symptoms which are strange and unknown to him. During his first year he is beginning to get a grasp of his new duties. During his second and third years he is perfecting himself in the knowledge of tropical surroundings and diseases, and by the time he has grasped them and thoroughly understands them back he goes to England, where, perforce, he forgets many of the valuable lessons acquired during his Indian tour. The question of attendance on the men of the various regiments, batteries, &c., to be transferred to the Home Establishment could be easily arranged for by handing these duties over to medical officers of this new service going on leave. This would also be an immense boon to them and save them the terrible expense of passages for themselves and families, which so often makes such inroads on their slender resources. The Home Medical Service I would run on much the same lines as the Indian, making the Colonial Medical Service its reserve and the colonies its training ground."

Although nominally civilians, many colonial surgeons, especially in the African colonies, see far more fighting than usually falls to the lot of an officer of the R.A.M.C., and it is unjust that they should be debarred from the honours and glories incidental to a military career. Moreover, the special sanitary training of the R.A.M.C. would be as valuable to the officer when acting as a colonial civil surgeon, as the increased experience in ordinary medical and surgical practice would be to him when serving in a military capacity. Most important of all, it is difficult to see how in any other economical fashion a sufficient military medical reserve can be secured for our Colonies.

His remarks on India are equally to the point. Owing to linguistic difficulties, it is indispensable that all branches of public service of that dependency should join for continuous service, and the medical departments are the only branch in which this is not enforced. The officers of the Royal Engineers serving there, for example, "elect for continuous service in India," and it is only in the medical department that we find the extraordinary spectacle of two distinct sets of medical officers, one only of which is capable of serving with all corps of the army, while the other is quite unavailable for service with the native regiments that form three-fourths of our Indian army.

The "Sanitas" Company, Limited.

At the Annual General Meeting (28th in number) of the "Sanitas" Company, Limited, held at Locksley Street, Limehouse, London, E., on March 1st, Mr. C. T. Kingzett, F.I.C., F.C.S., presiding, the Chairman remarked upon the steady growth of "Sanitas" in public favour, and while it was still regarded, from an all-round point of view, as the standard disinfectant (being the only preparation which combined in itself all the properties that could be desired for sick-room and household applications), it was necessary for the Company to meet competition from all sides. Hence, as the result of long investigation in their laboratories, the Company was about to introduce a new disinfectant to be known as "Bactox," which would favourably compare with the strongest known bactericides hitherto available, having a guaranteed co-efficiency of from thirteen to forty, as compared with pure carbolic acid. It was described as a neutral non-corrosive, saponaceous preparation, and having regard to its great germicidal strength and price would be found cheaper in use and as strong as, or stronger, than any competing article on the market, and devoid of all objectionable qualities. They would, therefore, in future, be able to offer to the public and sanitary authorities the choice of the best disinfectant for household and sick-room purposes on the one hand, and the strongest germicide for rough disinfecting and surgical use on the other hand.

Personal Notes.

R.A.M.C.

The following R.A.M.C. officers have been selected for increased pay: Lieutenant-Colonels Townsend from July 22nd, Woodhouse from August 26th, and Rowney from October 4th, 1905.

Colonel Leake, R.A.M.C., embarked in the *Sicilia*, on February 3rd, returning to India from sick leave.

Lieutenant Webb, R.A.M.C., remains at home on extended leave until August next.

Lieutenant-Colonel Reade, R.A.M.C., comes out on posting to the Secunderabad Division.

Lieutenant-Colonel J. B. Winter, R.A.M.C., on his arrival from England, will be attached to the Meerut Station Hospital for duty.

Colonel Trevor, R.A.M.C., is appointed Hon. Surgeon to the Viceroy, *vice* Colonel W. S. Pratt vacated.

Indian Medical Service.

Major L. Rogers, I.M.S., Officiating Professor of Pathology, Medical College, Calcutta, is allowed privilege leave for twenty-seven days, with effect from February 19th or subsequent date.

Captain J. M. D. Megaw, I.M.S., Officiating Resident Physician, Medical College Hospital, Calcutta, is appointed to act as Professor of Pathology in the Medical College, during the absence, on leave, of Major L. Rogers, I.M.S.

Captain H. B. Steen, I.M.S., Officiating Civil Surgeon, is placed on special duty at the Medical College, with effect from January 10th.

Captain C. F. Weinman, I.M.S., Officiating Civil Surgeon, is placed on special duty in connection with plague in Belear, from December 25th, 1905.

Captain H. M. Melhuish, I.M.S., whose services have been placed at the disposal of this Administration, is appointed to officiate as Superintendent, Central Jail, Jubbulpur, during the absence on leave of Captain F. D. Browne, I.M.S.

Captain V. E. H. Lindesay, I.M.S., is allowed privilege leave combined with leave out of India for thirteen months and twenty days, viz., privilege leave for one month and twenty days, and leave out of India on medical certificate for the remaining period, with effect from November 10th, 1905.

Major F. O'Rinealy, I.M.S., Officiating Civil Surgeon of Darjeeling, is confirmed in the appointment with effect from September 23rd, 1905, *vice* Major F. P. Maynard, I.M.S.

Captain R. L. Hagger, I.M.S., furlough for eight months.

Major A. E. Roberts, I.M.S., is confirmed as Secretary to the Director-General, I.M.S.

To be Major: Captain Herbert St. John Fraser.

Lieutenants to be Captains: William Samuel Jagoe Shaw, Charles Seymour Parker, Harold Holkar Broome, Frederick Norman White, Charles Gibbons Seymour, Davis Heron, Thomas Corrie Rutherfoord, Henry Crewe Keates, Leethem Reynolds, Ernest Charles Taylor, Richard Arthur Needham, Dwarko Prasad Goil, James Kirkwood, and Alfred Whitmore.

Home Department.—Colonel Macrae, I.M.S., is confirmed as Inspector-General, Civil Hospitals, Bengal, and Colonel King, I.M.S., as Inspector-General, Civil Hospitals, and Sanitary Commissioner, Burmah, both with effect from April 29th.

Major Lamont, I.M.S., Professor, Lahore Medical College, is granted furlough out of India from March 20th to June 30th next. Captain G. E. Charles, I.M.S., officiates as Professor of Anatomy, Lahore Medical College, *vice* Major Lamont.

Captain W. M. Houston, I.M.S., to act as Personal Assistant to the Surgeon-General with the Government of Bombay. Captain J. H. McDonald, I.M.S., on relief, to act as Presidency Surgeon, Second District, and Marine Surgeon and Superintendent, Lunatic Asylum, Colaba. Dr. F. M. Gibson, Medical Officer, attached to the Plague Research Laboratory, Parel, is granted three months' privilege leave combined with twenty-one months' furlough from the date of relief.

Privilege leave for two months and twenty-one days, in combination with furlough for eight months and nine days, is granted to Captain F. D. Brown, I.M.S., Superintendent, Central Jail, Jubbulpur, with effect from the afternoon of February 14th.

India Office: Arrivals Reported in London.—Captain J. W. F. Rait, I.M.S., B. Major C. E. L. Gilbert, I.M.S. Major C. R. M. Green, I.M.S., B. Lieutenant-Colonel R. J. Baker, I.M.S. Captain F. D. Brown, I.M.S. Captain R. L. Hagger, I.M.S. Major R. H. Castor, I.M.S.

Extensions of Leave.—Captain D. C. Kemp. I.M.S., M., special and study leave commuted to furlough on Med. Cert. for one year. Captain H. B. Meakin, 6 m. Med. Cert., R.A.M.C. Major H. Austen-Smith, I.M.S., B., was on study leave from October 9th, 1905, to February 9th, 1906. Captain E. L. Perry, I.M.S., B., was on study leave from September 1st, 1905, to December 31st, 1905, 4 m., M.C. Lieutenant-Colonel J. Maitland, I.M.S. M., 6 m., M.C., the period beyond 3 m. and 17 days being extraordinary leave.

Uncovenanted Medical Department.

Mr. S. Higginbottom to be Superintendent of the Government Leper Asylum at Naini in the Allahabad District.

Colonial Medical Service.

Lehfeldt.—R. H. Lehfeldt, D.Sc.Lond., B.A.Camb., Professor of Physics in the Transvaal Technical Institute, Johannesberg.

Gibbs.—H. J. Gibbs, L.R.C.P., M.R.C.S., M.P.C., Resident Surgeon to the Tan Toch Sing's Hospital, Singapore.

Singer.—C. Singer. M.B., B.C.Camb., Resident Medical Officer to the Government General Hospital, Penang.

DOMESTIC.

Births.

Graves—At Kamptee, C.P., on February 24th, 1906, the wife of Major D. H. Graves, I.M.S., of a son.

Marriages.

A marriage has been arranged between Captain Cecil Maddock, Indian Medical Service, 43rd Erinpura Regiment, son of the late Canon Maddock, M.A., Fellow of Clare College, Cambridge, and Alice Edome, daughter of the late Rev. T. J. Monson, M.A., and the Hon. Mrs. Monson, of Ashlyn, Leighton Buzzard.

A wedding took place at Dehra Dunn on February 5th between Captain George Hutcheson, Indian Medical Service, eldest son of Colonel Hutcheson, Indian Medical Service, retired, and Miss Lilian Annette Reynolds, youngest daughter of Mr. and Mrs. Reynolds, of Chandbagh, Dehra Dun.

Clarke—Adams.—At St. George's Church, Agra, on February 15th, 1906, by the Rev. W. Kitching, M.A., Chaplain of Agra, Captain J. B. Clarke, Royal Army Medical Corps, to Violet Grace Seymour Adams, M.B., C.M.(Edin.).

Burke—Reid.—At Christ Church, Rawal Pindi, on Wednesday, February 21st, 1906, by the Rev. H. A. C. Herbert, Captain Bernard Bruce Burke, R.A.M.C., to Anne, younger daughter of Surgeon-General A. Scott Reid, C.B., I.M.S., Principal Medical Officer, Northern Command.

Cameron—Robinson.—At the Cathedral, Bombay, on Friday, February 16th, 1906, Alexander Cameron, M.B.(Lon.), Indian Medical Service, second son of Alexander Cameron, M.D., of Cleethorpes, Lincolnshire, to Charlotte Eccles Mostyn, third daughter of the late Arthur Robinson, Esq., of Kemp Town, Brighton, and of Mrs. Robinson, Olton, Warwickshire. (Indian papers, please copy.)

Southon—Young.—At St. Thomas's Cathedral, Bombay, on February 16th, 1906, by the Rev. Harold Foote, Captain Charles E. Southon, I.M.S., 57th Rifles, F.F. Peshawar, to Agnes McLeod, younger daughter of John H. S. Young, Esq., Edinburgh.

List of Indian Medical Officers in Military Employ on Furlough.

OBITUARY NOTICE.

Thomas Edmonston Charles, M.D., LL.D.Edin., F.R.C.P.Lond., Honorary Physician to the King; Surgeon-General, I.M.S.

It is with sincere regret, which will be shared as a personal sorrow by many of our readers, that we have to record the death of Dr. T. Edmonston Charles, at Flushing, near Falmouth, at the none too ripe age of seventy-two

Dr. Charles was the son of a clergyman of the Established Church of Scotland, and was born in Calcutta in 1834, but in accordance with the usual custom, was at an early age sent home for education.

Electing the medical profession as his future career, he entered the University of Edinburgh, and graduated as M.D. and L.R.C.S. in 1855. His early connection with India naturally led to his deciding to follow his father's footsteps to the "land of regrets," and accordingly in the following year he joined the medical service of the Hon. East India Company.

The young medical recruit's admission to the service came just before the most exciting period of Anglo-Indian history, and before he had been a year in the service he found himself in the thick of the desperate struggle for existence that occupied the years 1857 to 1859.

His old friend and brother officer, Sir Joseph Fayrer, who contributes to the *British Medical Journal* a long and sympathetic notice, gives the following abstract of his services:—

"Soon after arrival he was attached to the 1st Bengal Fusiliers, served with them during the campaign of 1857-8, and took part in the celebrated march from Dugshai to Umballa. He was in medical charge of 400 men of that regiment and two squadrons of H.M. 9th Lancers, forming the advanced brigade of the army; was present with the regiment at the battle of Badlee ka Sarai on June 8th, 1857, and throughout the entire siege of Delhi till its final capture on September 20th. He accompanied the column under Brigadier J. G. Gerrard, C.B., into the Rewaree District against the Jeypore and Jodhpore rebels, and was with Sir Thomas Seaton, K.C.B., during his operations in the Doab; was present at the action of Gungeyree, the battles of Ruttialee and the affair at Mynpoorie. He was with the army on its second advance on Lucknow under Lord Clyde, and was with the storming party of the 1st Bengal Fusiliers, who took the enemy's first position at the Chuker Kotee and other points in their line of defence. He was present throughout the rest of the siege of Lucknow, and subsequently with the column under Sir Hope Grant, K.C.B., in Oude. He was mentioned in the despatch of Major Hume of September, 1859, and received the Indian medal, and clasps for Delhi and Lucknow. He was appointed Garrison Assistant Surgeon, Allahabad, 1859, Officiating Garrison Surgeon in 1859, and First Assistant to the General Hospital, 1860. Soon after this Charles returned to Calcutta and joined the General Hospital, where he held an important post. On the retirement of Dr. Wilson, of the Medical College of Bengal, from the post of Professor of Midwifery and Obstetric Physician, Charles was appointed in his place. He continued to perform the duties of this office for many years with great success and with much benefit to the cause of medical education in India. Not only as an obstetric but as a general physician Dr. Charles met with great success, and obtained a large practice in the Presidency. The trying and responsible duties of this work in an Indian climate in time produced their natural results, and rendered it necessary for him to resign, in 1880, an appointment which had been to him the source of much professional repute and its consequent advantages."

One of his last services to India was the foundation of the Eden Hospital, Calcutta, which has since become one of the most important gynæcological institutions of the empire.

Retirement to Dr. Charles, however, by no means implied a cessation of work, which, indeed, in a man of less indomitable energy would probably have resulted in downright illness, but was simply a transfer of his labours to more favourable climatic conditions. He settled first at Cannes and afterwards at Rome, and was busily engaged in practice in each of these favourite resorts. With all this he found time to show himself a learned archæologist and an enthusiastic mountain climber. After twenty-two years' more work in these fields of activity, finding, as most men must at an earlier age, that a man of sixty-eight can scarce expect to be able to work as hard as younger men, he decided to retire to the mild climate of Falmouth, were he remained until the end of an exceptionally strenuous life. In Flushing, close by the old Cornish town, he found a charming resting place, an old Georgian villa, with a sunny garden running down to the beautiful estuary of the Penryn river,

where his trim 3-tonner lay moored. Here the veteran might often be seen amongst his roses or busied in demonstrating the marvellous mildness of the climate by cultivating tropical plants in the open. With such surroundings it was characteristic that he should become a keen yachtsman, and winter or summer, blow high, blow low, scarce a day passed without his passing several hours afloat. Besides this he showed active interest in the local medical and scientific institutions, and but a few days before his death was asked to permit himself to be elected as President of the South-western Branch of the British Medical Association. His contributions to medical literature were numerous and valuable, notably his revision of the Sydenham Society's translation of Marchiafava, and Bignami's work on malaria.

To such of us of a younger generation who enjoyed the pleasure of his personal friendship, nothing could be more stimulating than the example and conversation of one who, in spite of failing physical strength, showed himself to the last conversant with the latest developments of tropical medicine. Like most truly lovable men, Dr. Charles could be a sturdy fighter when he chose, especially when his strong sense of right and justice was aroused in the interests of others, and perhaps his last contribution to medical literature was his able statement of the facts of the unfortunate dispute as to priority between Prof. Grassi and Major Ronald Ross. So conclusive was his handling of the question that it practically secured the verdict of scientific Europe in Ross' favour, and the controversy practically died a natural death from the date of its issue.

Dr. Charles had been failing in physical strength for some time, but the end came rather suddenly. During the last few months he had had several short attacks of fever, possibly recrudescences of malaria, and these left him very anæmic. Still, when his old comrade, Sir Joseph Fayrer, visited him he could find no signs of organic disease, and there is no doubt that Dr. Charles' pathetic diagnosis of his own case was quite correct: "I am quite well, only the machinery is worn out." It is consolatory to know that his last days were marked by but little suffering, and that his end was such as must be desired by all men of science: to retain intellectual activity to the last, and to pass away simply because the physical organism had not rusted but worn out.

Through the kindness of Mrs. Charles we are enabled to present our readers with a striking portrait of this veteran tropical physician, who was, we know, the personal friend of so many of our readers.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Annales de l'Institut Pasteur," 1905, p. 715.

Schneider, L. E., and Buffard, M., after examination of affected animals on both continents, state that the trypanosomiasis of horses and donkeys in Algeria is identical with the "dourine" met with in various countries of Europe.

"Zeitschr. f. Hyg.," T. li., 1905.

YELLOW FEVER IN BRAZIL.

Otto, M., and Neumann, R. O. There is comparatively little new in this memoir, which contains the usual descriptions of Stegomyia, &c., with some excellent plates. They succeeded in carrying some of these mosquitoes to Hamburg, and breeding them in a hothouse through a certain number of generations. They find that eggs kept dry on filtering paper lose their vitality comparatively quickly if the temperature of the air is high, but survive some time if it be cooler. However, they do not think that there is any danger of their breeding on board ship even in the case of wooden vessels, as bilge water is too salt for the larvæ to live in. They also conducted some experiments to ascertain the possibility of infected mosquitoes being carried about in luggage, and come to the conclusion that there is little or no danger of such an occurrence. They did not succeed in discovering any new specific organism, and, like many others, quite failed in their attempts to cultivate the *Bacillus icteroides*, nor did they have any better fortune in experimenting with the 4 μ bacillus of Durham and Myers.

"Journal American Medical Association," February 3, 1906.

TREATMENT OF CHOLERA.

Ussher, C. D., acting upon Koch's suggestion that quinine should be tried in the treatment of cholera, has met with marked success in the outbreak of cholera in the Philippines; as many as 90 per cent. of the patients recovering. The plan of treatment was as follows: Sulphate of quinine ten grains every hour until the rice-water stools disappeared, and bile is passed in the motions. For suppression of urine, friction of the limbs, hot fomentations, dry cupping over the loins, and sweet spirits of nitre are useful. When evidences of the circulation failing supervened, subcutaneous saline injections prove beneficial. The sulpho-carbolates of zinc, lime, and soda in equal quantities, given at intervals of from two to four hours, are efficient when irritability of the bowel persists, with a foul odour of the evacuations.

"Revue Suisse de Zoologie," 1905, p. 415.

SOME TAPEWORMS OF THE CHIMPANZEE.

Bourquin, J. As the anthropoid apes have been found useful in experiments in connection with the investigation of sleeping sickness, the above reference may be of interest to those engaged in the investigation of that disease.

"Vierteljahrschrift der Naturforschenden Gesellschaft Zurich," 1905, p. 163.

MIGRATION OF TRICHINA EMBRYOS.

Stäubli, C., who is in agreement with the previous observations of Akanazy, traces the embryos from the gut into the lymph channels and so to the thoracic duct, whence they are carried into the blood-vessels, and so to the muscles, where they become encysted. Naturally, the most active muscles being most vascular, arrest a disproportionate share of the intruders.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the JOURNAL OF TROPICAL MEDICINE should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communications.

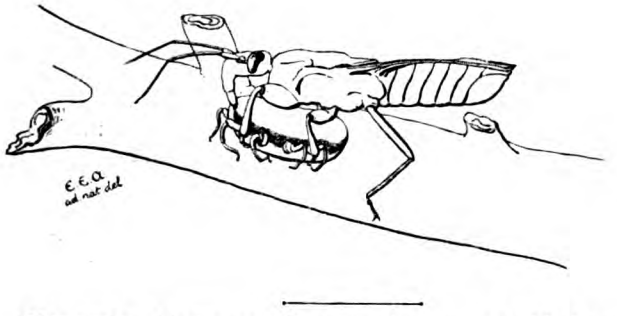
AN INSECT ENEMY OF THE DISSEMINATOR OF HUMAN TICK FEVER IN ANGOLA.

By Ernest E. Austen.

Zoological Department, British Museum (Natural History).

Among a consignment of blood-sucking and other insects received in August last from Benguella, Angola, and forwarded by Dr. F. Creighton Wellman, is a specimen concerning which the sender wrote as follows: "I found this insect on June 22nd, 1905, while studying a tick, *Ornithodoros moubata*, Murray, specimens of which I sent you some time ago. It was running about on the sticks composing a pig-sty, where I was collecting ticks. My attention was attracted by its singular appearance and movements; suddenly it entered a large crack in a stick, where it remained for some seconds. Since I could not clearly see what it was doing, I had the stick split open, when I found the insect holding a tick with its four anterior legs (which you will see are provided with curious paddle-like structures evidently designed for this purpose) and sucking blood from it by means of its powerful piercing proboscis, which it had inserted deeply into the tick. The animal was so intent upon its prey that I was able to carry it to a house without disturbing it, and to observe its actions for some time. I also exhibited it in the act of sucking blood from the tick to Mr. W. E. Fay, B.A., a former student at the London School of Tropical Medicine. When placed in a killing bottle the insect withdrew its proboscis from the tick, but still clutched it with its first two pairs of legs. I mounted it in this position, and you will notice the wound in the tick near the margin of its body."

The specimen referred to in the foregoing interesting note by Dr. Wellman is a hemipterous insect, or bug, belonging to the family *Reduviidæ*, and to the species known as *Phonergates bicoloripes*, Stål. It is still grasping its victim in the manner described above, but the tick has become shrivelled and distorted in consequence of drying. The subjoined sketch will, however, perhaps make the position of the destroyer and its prey, as well as the general appearance of the former, sufficiently clear.



Phonergates bicoloripes, Stål, preying on *Ornithodoros moubata*, Murray.

The following is a brief description of Dr. Wellman's specimen of *Phonergates bicoloripes*, a species which was originally described from "Caffraria," and of which the Museum collection includes three examples from the Zoutpansberg district of the Transvaal. *Length*, 18½ mm.; width of thorax at base of wings, 5¼ mm.; width of abdomen (on which, when insect is at rest or walking, the wings lie closed one over the other like the blades of a pair of scissors) 5 mm. *Colour:* thorax metallic purple; wings (which when closed conceal abdomen when insect is viewed from above) deep velvet-black; hind-legs bluish-black; front and middle femora and front tibiæ coral-red, with tips of femora, and base and tip of front tibiæ, black; middle tibiæ, brownish. The front and, to a lesser extent, the middle femora are swollen. The tips of the front and middle tibiæ are provided on the underside with a large spongy pad, which assists the insect in obtaining a firm grip of its prey.

The bugs of the family *Reduviidæ* prey, as a rule, upon insects of all kinds, and the writer is informed by Mr. W. L. Distant that he has even seen a specimen preying upon a weevil, *i.e.*, a beetle belonging to the family *Curculionidæ*, the intense hardness of the chitinous covering of which is well known. It is, of course, possible that by this time Dr. Wellman has met with other instances of *Phonergates bicoloripes* attacking *Ornithodoros moubata*, but it is extremely unlikely that the bug preys especially upon the tick in question. In all probability the specimen observed by Dr. Wellman happened to alight close to a tick, and seeing the latter crawling at once pounced upon it.

SUGGESTIONS FOR THE MAINTENANCE OF HEALTH BY WOMEN IN THE MISSION FIELD.[1]

By Mary A. D. Scharlieb, M.D.Lond., B.S.

The subject can be considered under the following heads:—

(1) *Preparation for Work in the Mission Field.*
(*a*) A good rest and general "getting fit."
(*b*) Examination and care of teeth, eyes, skin.
(*c*) Medical examination and advice.
Special examination of intending wives.
(2) *Selection of Candidates.*
Reasons for declining offers—age, disease, defects, deformities, nerves, bad family history.
(3) *Allocation of Candidates to Special Work.*
(4) *Care of Health on Active Duty.*
(*a*) Clothes, food, drink, purification of water.
(*b*) Choice and construction of houses; selection of site.
(*c*) Amount of work, exercise, and rest.
(*d*) Care of minor ailments—chills, slight fever, diarrhœa, toothache.
(*e*) Dangers of mosquitoes, flies and ticks.
(*f*) Annual holiday.
(*g*) Daily dose of quinine.
(5) *Care of Health when on Furlough.*
(*a*) Medical examination and advice on arrival.
(*b*) Choice of locality for holiday.

[1] Paper read at the Medical Officers of Missionary Societies Meeting, March 20, 1906.

(*c*) No deputation work on short furlough, and none on long leave until health is re-established.

(*d*) Medical examination some months before expiration of leave.

The maintenance of health in the Tropics depends greatly on

(1) The Preparation for Work.

Among the essentials of this preparation are the enjoyment of a good rest and the careful getting of body and mind into their best possible condition.

Many young women who offer themselves as candidates for mission work have already been considerably strained by other work or study. Many of them are teachers or medical students, some of them clerks, accountants, or domestic servants. In all such cases it is essential that an interval of several months should intervene between the old work and the new. If this precaution is neglected, the candidate may go out at the expense of the society, only to cause disappointment by an early breakdown.

It may be suggested that each society's medical adviser should enquire into the candidate's recent circumstances, work, and method of life. This would lead to advice about a holiday and where to take it. It must be remembered that many candidates have poor homes in crowded cities, and that a holiday spent in hard work in such surroundings is certainly not a "holiday" as intended by a medical officer or an advisory board.

It may be considered Utopian, but really each society should have its "home of rest," to which it could send its candidates and missionaries when necessary. This might possibly be arranged in connection with the hostel or training college which many of them already possess.

Medical Examination.—Of course each society has its medical officer, and several of them have advisory boards which have been the means of greatly lessening the death-rate of such missions as the Universities' Mission to Central Africa, and others working in specially unhealthy climates.

Many applicants for missionary service are overstrained from study and other causes and hence a preparatory term of rest is very essential to prepare them for the strain of tropical research.

Many of the great missions publish information as to the preservation of health in the form of a printed letter or pamphlet, but it is perhaps desirable that in each number of the missionary magazines there should be a short paper dealing with some practical point, such as the influence on health of mosquitoes, of excessive rainfall, imperfect protection from the sun, errors in diet, clothing and housing. No doubt the magazines are intended to arouse interest in the work of the mission, but they are so much read by the missionaries themselves that they would be good channels for the diffusion of information on such important subjects.

It also seems as if the committees of our societies need to be begged to consider more carefully the reports of their medical officers, and to give effect to their recommendations in the selection of candidates. They should also consider their advice as to the correction of certain defects, especially those of the eyes and teeth, and as to the necessity for vaccination in all cases, and of inoculation with typhoid or plague in some special instances.

In the case of young women proposing to go out out as the wives of missionaries, there should be a special investigation as to their fitness for maternity. The external measurements of the pelvis should be carefully taken with calipers, and, if any obvious deformity exists, a further examination under anæsthesia may sometimes be proposed: loss of valuable lives and much hindrance to work being saved if it is clearly understood that in any given case the wife of a missionary is likely to need specially skilled assistance, and must therefore go for confinement to some centre where such assistance can be secured.

(2) Selection of Candidates.

In the selection of candidates the medical officers of missions are greatly assisted by the excellent tables of questions supplied by most missions, unfortunately not by all. These questions should be as minute and searching as are those proposed by life insurance societies. This precaution is the more imperative because candidates, in their zeal for service, sometimes, it may be unconsciously, give a most misleading account of their health and physical capacities.

There are certain facts in a candidate's history which must lead to rejection, while a still larger number make it necessary to give her acceptance only in the event of her fulfilling certain conditions. Among the former are unsuitability of age. Candidates who are too young and immature are a constant care to the older members of the mission, and they are specially liable to certain forms of illness. Candidates much above 30 years of age are generally unsuitable, because they fail to adapt themselves easily to trying climatic and social conditions; they have become more or less set in their habits of life, and do not readily alter them, as is really necessary in the different conditions of climate and surroundings.

The older candidates, as a rule, find more difficulty in learning new languages, and are less fitted to understand the philosophy and religion of those to whom they are sent. Judgment may be better in middle life than in youth, but memory, power to learn, adaptability, and readiness of sympathy are less. Besides all this, there is a constantly increasing chance that organic disease or chronic error of function may be present, rendering the individual less able to withstand the evil influences of bad climate and poor food.

Another point to be carefully considered is the existence of some defect which is likely to impair usefulness, such as lameness, lateral curvature of the spine, flat feet, and any marked deformity.

Amongst the causes of conditional acceptance which may be noted are certain defects which impair usefulness, chiefly those of the special senses, such as deafness and errors of refraction. Deafness in even a minor degree makes the acquirement of a new language difficult, and defective eyes are unduly tried by unfamiliar symbols of language. To all this must be added the fact that when general vigour diminishes under the influences of bad climate, inadequate or unsuitable food, and trying work, all special dis-

abilities become more evident, and lead to breakdown just as surely as do constitutional unsoundness or attacks of illness. Probably people who have sharp hearing and normal sight are quite unconscious of their advantages in the battle, and do not know how much more difficult things are for less favoured colleagues. Unless, therefore, such defects can be remedied, the candidate should be rejected in justice both to herself and to the society.

The undesirable possession of "nerves," or the being, what people call, with unfortunately a certain degree of approbation, "very sensitive and highly strung," is generally a bar to effective and enduring work, whether in community or as an isolated missionary. It is a very serious question as to how far the prolonged and heavy burden of modern education is responsible for this condition. This is not the place to discuss the distribution of responsibility among mental training, the unconscious education of home, and real hereditary peculiarities, but no matter how produced, such a condition of the nervous system is a very real hindrance to work, whether at home or abroad, and should be regarded as being sufficient to debar a candidate from acceptance.

In the same category must be put bad family history, especially if that family history be a nervous one. No doubt the different parts of the mission field have different characteristics, and there are certain portions of it that are specially trying to the nervous system, *e.g.*, Japan, North China, and Burmah. This leads on to the next subject—

(3) Allocation of Candidates to Special Work.

No doubt in many instances a candidate offers for some special work, and wishes, for instance, to be sent to Japan; but surely an essential part of the duties of the medical advisers to the societies is to consider the fitness of the candidate not only with reference to mission work in general, but for that special branch which she is anxious to undertake. To send a girl of obviously unstable nervous constitution to Japan would appear to be as wrong as to send another who has already suffered from malarial infection to the West Coast of Africa. All tropical climates have certain drawbacks in common, such as heat, undue moisture, presence of mosquitoes and other undesirable insects, but in addition there are peculiarities in nearly all these climates, and in advising societies as to the allocation of missionaries, it is desirable that the medical officers should know all that is possible for them to know as to these peculiarities, and also that they should study each individual case with a view to distributing the material as suitably as possible.

(4) Care of Health on Active Duty.

There is a very regrettable waste both of life and health which is not really unavoidable. The climate in which the worker finds herself may be far from ideal, but in too many instances the missionaries, especially the younger missionaries, appear to absolutely court disaster. They remind one so much of the fatal remark made by Lord Methuen at the commencement of the South African War; he said: "This is a war in which it will not be etiquette to take cover"; there spoke no doubt the courageous and gallant commander, but not the wise and successful leader of men.

Probably all doctors who have seen much of young women missionaries in the Tropics have found in them an heroic disregard of the most obvious precautions which ought to be taken as a matter of duty and common-sense by all residents in tropical climates. Some of this recklessness may be due to fiery zeal, beautiful and impressive, but not useful, which is more or less inherent in young people, but much of it is also due to the appalling ignorance of sanitation, hygiene, and physiology, so common in the present day. "The people is destroyed for lack of knowledge, how shall they know unless they be taught," and who is there to teach them. In our schools, whether for rich or poor, everything is taught, from the alphabet to the piano with the exception of what really concerns the pupils to know, their duty to God and their duty to man, including their own bodies. How can we expect people who live in rooms habitually over-heated and ill ventilated to understand the value of fresh air? How can we expect girls who have never been in the kitchen and who know nothing about food to make thrifty and intelligent mistresses of missionary families or wise home-sisters to a community.

As to the question of drink, there is no doubt that the great majority of people working in the Tropics would be much the better for avoiding the use of alcohol as a beverage. Missionaries generally comply with this rule, probably more from a desire to set a good example to their scholars and converts than from motives of hygiene; there is, however, no doubt of the folly of taking alcohol in climates where the inevitable weariness and lassitude are so likely to lead people on from a harmless minimum to a maximum which is incompatible with health of body or mind.

To maintain health in the Tropics many habits of daily life need revision. Ordinary English folk eat too much meat, and, indeed, too much food altogether. The attempt to do this in a tropical climate is sure to lead to disorders of digestion and chronic ill-health. Plenty of milk, bread, butter, vegetables, and fruit, with relatively little meat, would be a more suitable dietary than the heavy breakfast, lunch and dinner which is usual with Europeans in India.

Another very serious danger to health in the mission field is the difficulty of procuring good milk and pure water.

Milk is not attainable in some places, in others it is very poor in proteids and in fats; in nearly all stations it is liable to contamination with dirty water, or by being drawn from unwashed udders by dirty hands. The wonder is, not that typhoid, dysentery, and other microbial diseases are conveyed by milk, but that any one escapes infection. The only way to guard against such illness is for some responsible person to see the cows milked and to insist on the observance of all reasonable precautions.

The storing of milk is a difficulty only less urgent than ensuring its original purity. In hot countries milk is a highly putrescible fluid and rapidly becomes unfit for use. This difficulty, like the difficulty of guarding against its containing germs of tubercle and other diseases, is met to some extent by boiling or

sterilising. Neither of these methods is wholly satisfactory, for even sterilisation affects the food value of the milk.

Water is the staple drink and also the most frequent vehicle of disease. The source of water supply, whether river, well, or tank, is too often open to the grossest fouling; one and the same collection of water being used as sewage carrier, as washing ground, and as drink for man and beast.

The carelessness of all concerned, Government, missionaries, European residents and natives, is marvellous. The merest common-sense should enforce the rule, "The rain to the river, the sewage to the soil," but no, those who should know better allow the sewage to enter the river, while the rain collects in shallow depressions round the houses. Typhoid, cholera, dysentery and malaria follow in the ordinary course of Nature, and those whose ignorance and carelessness have caused the catastrophe talk of heroic self-sacrifice and the deadliness of the climate—truly "the people is destroyed for lack of knowledge."

The water supply can never be trusted, and the only safeguard is to drink none that has not been boiled and kept covered from dust and other sources of contamination.

Choice of Houses, Construction of House, Selection of Sites.—In well-settled countries, such as many parts of India and China, the individual missionaries find their houses ready for occupation, and have no responsibility as to choice of site or construction of house. A heavy responsibility does, however, rest upon those who choose the house itself. From a desire that the missionaries should live as much as possible amongst their people, the heads of missions too often select houses in the native quarter of the town. Such houses are very likely to be built on native principles of sanitation and comfort, which it is needless to say are neither suitable nor desirable for Europeans. In many cases they are in immediate proximity to the open gutter, which serves the purpose of a general sewer; ventilation is conspicuous by its absence, and there is a general want of convenience and comfort. Far worse than this, there are the many diseases which are immediately communicable from man to man, either directly or through the mediation of mosquitoes, flies, ticks, &c. Europeans living in the native quarter are exposed to all these dangers, and also suffer from the absence of open spaces, proximity to the country, or the sea-shore.

Of course, every one understands the desire of the missionaries to be near their work and amongst their people; much fatigue and expense is saved by not having to make journeys to and fro, and another inducement is undoubtedly the hope that by living a Christian life in the midst of their heathen neighbours their example may be like "the city set on a hill which cannot be hid." All the same, it is to be feared that the balance swings entirely towards evil rather than good, for it is not possible for Europeans living under such circumstances to maintain their health, and with the loss of health comes loss of efficiency, and in many instances loss of temper and of many of the moral qualities which are so necessary in dealing with the heathen and with converts. It should therefore be a matter of principle with those responsible for such matters, that missionaries' houses should be sufficiently removed from native quarters to enjoy an abundance of air and sunlight; they should, if possible, have upper rooms in which to sleep; the trees should not be permitted to grow too close to the house; and all shallow tanks and puddles should be filled in. Beyond all these things, it is necessary to see that the servants' quarters are as far removed as possible from the house. It is now well known that mosquitoes are the carriers of malarial infection, and that few native children are not hosts of the malarial parasite; if, therefore, the servants' quarters are near to the house, there is nothing to prevent the mosquito from carrying the malaria from one to the other.

There is real sense as well as economy in having but little furniture and no hangings in tropical houses. Any curtain or garment hanging up is simply a hostel of which the mosquito avails itself freely; sheets and clothing having been hung in the sun to dry ought to be folded up and put away into bureaux or boxes, for when they hang in the sleeping rooms they become a positive danger.

It is a distinct advantage to have fine woven wire to fit into the windows and doors, made so that they can be open in the day and closed at sundown. The mosquito is chiefly a nocturnal creature, and ought, if possible, to be excluded from the dwelling.

An excellent modern device is a sort of small tent of gauze within which a chair and table can be placed. This enables any one to read or write without the annoyance and danger of being bitten by mosquitoes. Among minor safeguards are the rubbing of the skin with oil of lavender and the wearing of high boots, putties, or gaiters.

It often happens that in breaking fresh ground and laying the foundations for a new mission station, the responsible head has to choose a site which shall be suitable for the mission houses. This should be, if possible, on a sloping ground with no houses above it. The servants' quarters should be a considerable distance away and at a lower level. It is also most desirable that there should be no half-way house between the European and native quarters, for the mosquito is capable of flying about 500 feet., it then settles on some vantage ground, and gathers strength for a further flight. Abundant provision should be made for dealing with refuse and with household slops. It is absolutely immoral to permit excreta and rubbish to foul running water or to enter a lake, tank, or well. There is no doubt that the earth system is the only one practicable, but this demands very careful management or the heavy rain will wash away both earth and excreta, fouling all the ground in the neighbourhood.

Another point that should engage the earnest attention of the selector of a site is that there should be no swamp or marsh in the neighbourhood. There was a great deal of unconscious wisdom in those of old time who spoke of malaria as "marsh fever," for although it is by no means a miasma or an emanation from marshy soil, yet shallow and stagnant water affords a breeding ground to the mosquito, which is itself the cause of the scourge.

It is curious to look back to one's student days and to remember how we were cautioned to advise

travellers to encamp to the windward of groves of trees or of running water; of how they were advised to kindle fires between themselves and the marsh, and how it was supposed that the deadly miasma was of so particulate a nature that it it did not readily pass through the meshes of a mosquito net, in the same fashion as it was known that fire-damp did not pass through the closely woven wire gauze of the miner's safety lamp. All these facts were true, but our interpretation of them was erroneous.

In the matter of the construction of a house much must depend upon the materials available, but it has been abundantly proved, especially in the history of the Universities' Mission to Central Africa, that the health of the missionaries is much more stable in well-built houses whose walls are thick, whose foundations are well laid, and in which there is an abundance of air without draught and without exposure to wet mists. No doubt pucka-built houses are more expensive, whether they be fashioned of bricks, stone, or rubble faced with chunam. There was no doubt cheapness, immediate economy, and perhaps some romance in living in wattle and daub huts thatched with palm leaves; but after all, nothing in the mission is so valuable as the health and lives of its members, and therefore no expense within reason can be considered extravagant which really secures their safety.

Amount of Work, Exercise, and Rest.—There is no doubt that owing to zeal and enthusiasm outstripping discretion, many missionaries, and espepecially the younger members, are extremely careless about their health. When they first come out they are in most instances quite ignorant of the dangers of the climate, and even if they understood they would be disposed to think that their good intentions would protect them from harm. It is very difficult to persuade new-comers that the tropical sun is deadly, and that it is not safe to walk out (except in the very early morning and evening) without the protection of pith helmets, white-covered umbrellas, and dark glasses. It is also difficult to make new-comers understand that active and outdoor work ought to be accomplished as far as possible in the cool of the morning or evening, while the middle of the day should be devoted in part to learning the language or other mental occupations, and that, having in view the very early hour of rising in the morning, some two or three hours should be spent in rest.

Another danger which is not generally appreciated at its right value by the young and enthusiastic is that work of all kinds should be taken quietly and steadily, that there should be no rush or worry over it. Some of the young missionaries feel that every day spent in the acquisition of the language is a day lost to their Master's service, and they consequently are anxious either to scamp this most necessary part of their preparation, or to work so hard that eyes and brain are alike overstrained and injured. No one can say how many hours a day any one ought to work, this must be a personal question, for whereas one individual can work at the language with impunity for five or six hours a day, other less mentally robust individuals cannot do more than two or three hours without danger of "knocking up."

Exercise is a duty greatly disregarded, especially by women in tropical climates; they suffer much from lassitude, and the slightest exercise is liable to be accompanied by profuse perspiration, and by development of prickly heat; they are therefore disposed to shirk physical exertion as much as possible. This, of course, leads to indigestion, constipation, and frequently to sluggishness of the liver and headache. Unfortunately most people have an idea that these ailments are to be remedied by drugs, and they are very unwilling to follow the natural and proper course of increasing their exercise; others have a belief that any exercise beyond ordinary walking, such, for instance, as croquet, lawn tennis, and cricket, are of the world, worldly, and unworthy of the enthusiastic and devout missionary. It is quite necessary to persuade them that so long as they are under earthly conditions they need to take ordinary care of their health, and that the form of exercise which is found to promote that is the one by which they can best honour God. It appears to be greatly a matter of habit, for thousands of Europeans keep themselves in excellent health even in malarious and trying climates by taking regular and steady exercise, by working reasonably, by resting sufficiently, by eating suitable food, and in one phrase by "walking in the paths of physiological righteousness."

Care of Minor Ailments, Chills, Slight Fever, Diarrhœa, Toothache.—There is a good old saying, "Take care of the pence and the pounds will take care of themselves," and one would fain remind missionaries and other dwellers in tropical lands that if they would attend to slight ailments there would be a much better chance of remaining free from grave disease. Many an apparently trivial indisposition is either the commencement of real trouble, or at any rate prepares the way for catastrophe; *e.g.*, a heedless new-comer finds it delightful to sit on the roof of the house or on the verandah after the evening meal; they attribute no importance to their damp garments and perhaps chilly sensations; it is not until fever or other serious trouble develops that they can be brought to realise the unwisdom of their pleasant rest.

All rapid chilling of the skin, and dampness, even although slight, is of far more importance in tropical than in temperate climates, and ought to be carefully avoided, chiefly by wearing thin woollen garments next to the skin, and by providing light woollen or silken wraps to put on when driving after sundown, sitting out, and after getting hot with taking exercise.

A very slight deviation from health in the matter of indigestion or of diarrhœa should be carefully treated by rest and by minute regulation of diet. Of course the old wives' fables about the diarrhœa which became cholera can be classed with the similar fable of a quinsy which became diphtheria. We know that grapes do not grow from thorns, nor figs from thistles, but the gastric and enteric catarrh may prepare the soil for the germination of the vibrio of cholera, just as the inflamed tonsil is a ready breeding ground for Loeffler's bacillus.

Perhaps the heading of *toothache* may excite a smile, but it is one of the most harrassing and incapacitating of ailments, and seriously interferes with

the duties and happiness of life, and not only so, but when abscesses form at the root of the teeth and a condition of pyorrhœa alveolaris develops, the individual's standard of health will certainly be greatly lowered, and it is very probable that serious illness may follow. Dr. William Hunter has taught us the intimate connection between some forms of pernicious anæmia and oral sepsis, while other observers have pointed out a similar connection between oral sepsis and a form of rheumatoid arthritis.

(*e*) *Dangers of Mosquitoes, Flies and Ticks.*—Enough has probably been said of the dangers of mosquitoes and of some of the methods of minimising them, but a brief *resumé* may be useful.

It is now generally recognised that mosquitoes are the intermediate hosts of the parasites which cause malaria and yellow fever. Many experiments have been made, and the evidence inconclusive, men may live safely in the most malarious districts *provided* that they can protect themselves from the bites of mosquitoes. On the other hand, people may be bitten by infected Anopheles here in London, and will in due time develop malaria.

The great problems are:—

(1) How can the Anopheles be prevented from breeding near human habitations?

(2) How can Europeans defend themselves against the bites of these small assassins?

The Anopheles breed in shallow and stagnant water, therefore houses should not be built near any swamp or marsh, nor on ground in which there are shallow depressions liable to be filled by rains; the neighbourhood of irrigated lands is specially to be avoided. All marsh-land should be drained, if possible; puddles and shallows should be swept out and dried. Sometimes coating with a film of paraffin is easier. All windows and doors should be fitted with fine wire gauze shutters, which must be closed at sunset. The rooms should then be fumigated, and all parts of the sleeping rooms should be thoroughly searched and flapped with towels to disturb and kill any sleepy mosquitoes. All beds should have sound and good mosquito nets, and a portable canopy should be used by each individual in the evening—a canopy under which a table and chair can be placed.

Any one walking out after sunset should protect the feet and ankles with gaiters or putties, and all exposed parts of the body, such as the face and hands, should be smeared with lavender oil.

As said before, native huts must not be built near European houses, and native children must not be allowed about the house or verandahs.

It is also certain that disease may be propagated by various kinds of flies, and there is a fever known as "tick fever." One of the commonest troubles in some parts of the mission field is a particular form of purulent conjunctivitis, the infection of which appears to be carried by eye-flies. In this case, again, the fly would appear to be, at any rate, the agent by which the infection is transferred from natives to Europeans.

(*f*) *The Annual Holiday and the Home Leave.*—These breaks in mission service are absolutely essential to the maintenance of health and of efficiency. Most workers find that a yearly holiday is essential even in a temperate and healthy climate, still more is it urgently needed by those who work under the great strain and stress of a hot, moist climate, combined with heavy work, much anxious responsibility, and constant exposure to disease. In most cases a healthy holiday may be had each year by a visit to the hills, or by going for a sea voyage. Leave time should be enforced after two years' service in exceptionally bad climates and after five years in less trying stations.

(*g*) *Daily Dose of Quinine.*—When living in really malarial districts and on the march, it is right to take daily doses of quinine—two grains with the early tea, and one or two after lunch and dinner. Few people cannot take quinine in some form, and even the large doses which are necessary to prevent an expected attack may be taken without unpleasant consequences if mixed with hydrobromic acid. It is to be remembered that when once malarial infection has been established a recrudescence is easily provoked by chill, exposure to the sun, fatigue, and indigestion.

A patient suffering from malaria must be carefully protected from being bitten by mosquitoes, for they suck in the germs of the parasite with the blood of the invalid, and subsequently inject them with their saliva into other people. In this sense, and in this sense only, is malaria infectious.

(5) Care of Health when on Furlough.

(*a*) *Medical Examination and Advice on Arrival.*—It is impossible to urge too strongly that every missionary should be seen by the medical officer of the mission immediately on return from abroad. Cases constantly occur in which missionaries who have been invalided home at the end of their term of service fail to report themselves on arrival. The idea is that merely coming home will cure their ailments, and consequently they drag on, their dysentery becoming chronic, their malaria smouldering, and their anæmia scarcely relieved. They think they ought to be well, and act as if they were well, eating ordinary diet, incurring considerable fatigue, and steadily preparing themselves to join the ranks of the non-efficients.

If all missionaries were seen and examined on return and submitted their "health history" to the medical officer of their society, they would receive valuable advice and treatment which would generally ensure the re-establishment of their health, and enable them to return to the field with renewed health and capacity for work. In some few cases the medical officer or the advisory board would report that the missionary was unsuitable for the foreign field, and should be employed at home or struck off the active list. Such a decision, although no doubt reluctantly made and full of sadness, would often save the life of the missionary, and would defend the mission from serious pecuniary loss. No one should be permitted to return to the field who had suffered from blackwater fever, frequent attacks of ordinary malaria, repeated attacks of dysentery, and, above all, those whose nervous systems could not stand the storm and stress of climate and work.

The medical officers would also be able to advise returned missionaries as to work while on leave.

Some missionaries wish to employ part of their holiday in study; for instance, men desiring to take

holy orders, men and women doctors anxious to obtain superior qualifications or increased experience. In many cases this may be permitted, and the medical officer will be able to offer advice as to opportunities for study and possibility of assistance. In other cases the missionary may be able and willing to do deputation work, or otherwise to assist the society while at home, but no one should be permitted to work without being examined and passed as fit.

(*b*) *Choice of Locality for Holiday.*—Another point on which advice is likely to be needed, but is not likely to be sought, is on the subject of where to spend the holiday. Many missionaries are members of poor families, their relations live in small houses, badly situated and badly found in all respects. All of us can remember instances in which the weary, toil-worn missionary returns to a poor and comfortless home, to worse food than she had while at work in the field, and sometimes to be the domestic drudge, or the willing but most unsuitable nurse to a home invalid. Can it be wondered at that furlough so spent fails to do good, and that the missionary's subsequent record is disappointing? Modestly and simply as our brothers and sisters live in the field, inferior though the meat, bread and milk undoubtedly are, yet they enjoy perpetual open-air life, a comparatively abundant service, and a blessed absence of pecuniary cares. When they come home, the advantages of climate are sometimes greatly minimised by the circumstances of their homes. Some one on the home staff should know the circumstances of each member of the mission, and should be in a position to offer hospitality for a portion of the leave at a hostel or home of rest connected with the mission.

It might be possible in some missions to have a holiday fund from which grants could be made in certain cases to enable those who could not otherwise afford it to go to the country, seaside, or wherever the medical officer might think best.

(*c*) *No Deputation Work on Short Furlough and none on Long Leave until Health is Re-established.*—When missionaries come home for really short periods, say for six months or less, it is not desirable that they should do any deputation work. Their time for rest and refreshment is short, and should be spent in recovering health and elasticity; the policy of permitting them to work during short leave is mistaken and shortsighted. When the leave is longer, deputation work may be permitted, but only when sanctioned by the society's medical adviser. Some people, men as well as women, have no gift for public speaking, and suffer acutely from nervousness on such occasions. They should not be subjected to this trial.

(*d*) *Medical Examination some Months before Expiration of Leave.*—*Finally*, no missionary should be permitted to return to duty without the written sanction of one of the society's medical officers. This sanction should be sought in good time, otherwise unnecessary expense and annoyance are caused by the preparation of outfit and the securing of a passage.

Usually two months will amply suffice, for it is pretty certain that a missionary due to return to work in October should be able to pass the medical examination in August. It would usually suffice for the society to nominate a trustworthy practitioner in the nearest town to the place where the missionary was living.

SOME STRIKING FACTS ABOUT AN EASTERN CITY.

By R. H. Bremridge, M.A., M.B.Oxon., B.Sc.Lond.,

Bangkok, Siam.

Situated at the mouth of a very large river and in about the same latitude as Madras, is a city with about three-quarters of a million inhabitants. At least half of these are Chinese, and the remainder, with the exception of some other Asiatics and a few Europeans, is made up of Siamese. Bangkok, for that is the name of the city, is surrounded by flat, low-lying, very marshy country, and has a mean temperature of about 83·5° F., and a rainfall of 46·5 inches. Strong winds do not prevail, and there are many collections of water with a constantly smooth surface most convenient for the breeding of mosquitoes. Moreover, there are vast hordes of mosquitoes and many Anopheles among them. Everything would seem to have been arranged by Nature to promote malaria, yet there is very little in the town itself. Severe cases come in from the country, but among the genuine town-dwellers malaria is certainly far from common. An American doctor, of nineteen years' experience, stated lately that he did not think he had seen twenty cases of malaria among genuine town-dwellers. Such a statement is open to criticism, but it serves to show that malarial fevers are infrequent.

It is not possible to get the mortality figures or case incidence of any disease—there are no such records. However, by collecting the experience of credible European doctors in charge of the police, army, navy, jails, &c., &c., a shrewd guess may be formed.

The laws and regulations for the care of the public health are easily described. There are not any. Docketed away somewhere in a dusty pigeon-hole there may be some, but for all practical purposes the layman is never made to know them.

Running along the front of the houses are open drains, into which it would appear anything may be and everything is thrown. These drains empty themselves, when they are not stagnant, into the various canals, and the canals intersect the whole city, forming one of the chief methods of communication.

Many houses face on these canals and derive their water supply from them, and that not after any method of filtration, but directly. Such water is used not only for all domestic purposes, but also for cooking and drinking.

The central jail, in which are approximately 2,000 prisoners, empties its surface water and liquid refuse into a canal about the size of that in Regent's Park, London. The jail takes its water supply from the same canal, and at a place some few yards from the position of the sewage outlet.

For the general use of the town there is no water supply other than the canals. True, one or two arte-

sian wells have been already bored, but as yet they do not seriously, if at all, affect this statement.

Typhoid and Cholera. Typhoid is not a common disease, and cholera, though continually present, does not assume the proportions of even a moderate epidemic.

Be it known that the stench from the open drains is truly dreadful, and that during the dry season, when the canals are quite empty at low water, the flushing of many of them is practically a negligible factor. Yet it is quite usual to see men, women and children living and having their being alongside these drains, and in this atmosphere of stink. Moreover, they look and seem well.

Plague has recently appeared among us, and some European doctors predicted and feared terrible consequences. A case of plague has occurred here and there at lengthy intervals, but the records have not yet attained epidemic proportions, yet everything would seem to be in favour of the plague.

Some parts of the city, notably the Chinese quarter, is crawling with humanity. Here land is sold by the square inch. Everything that can be called a house is full from the floor to the ceiling, and the mainway between the houses is but a narrow path. There is no drainage, no water supply, no anything, and, strange to relate, no plague. Why, no one knows.

To deal with such a place according to the most elementary ideas of sanitation means its entire destruction as the only possible beginning, and this would cost about six times the annual revenue of the country.

Bangkok would be to a man of fixed ideas about sanitation nothing less than an awful nightmare, and yet it is not over unhealthy. Indeed, the general look of the European women and children is better than in many well-cared for stations in India. They are not pasty-looking and tired, and they are not ill.

It is difficult to resist asking one's self the question, whether it would not be unwise to interfere here, and graft a partial European system, almost inevitably indifferently carried out, on the present order of going. Now, there would seem to be some sort of natural balance set up between the contending micro-organisms, and that in the fight for existence among themselves they are protecting us "humans." To alter the whole place immediately, and put everything under human control, is impossible. The necessary engineering work is lengthy and the cost enormous. Half measures may mean a disturbance of the already existing balance, and the ultimate result a less healthy city. It must always be recognised that to disturb a natural arrangement unless you can see far ahead may in the end be most disastrous.

Witness the island of Jamaica. To kill the rats infesting the sugar cane the mongoose was introduced; the rats were exterminated; the mongoose then became a plague, and has got rid of all the lizards, harmless snakes and small birds. As a consequence insect pests abound, and among them is a troublesome tick, which destroys the cattle. This tick having had all its enemies removed by the mongoose flourishes luxuriantly. The last state of Jamaica is worse than the first. Bangkok may repeat the history of Jamaica. Improvements may not lead to such satisfactory results as were anticipated.

Give Bangkok closed drains and all that goes to make up a sanitary paradise, and Bangkok may during the years of changing have epidemic plague and epidemic cholera, and malaria in plenty. Be that as it may; constituted as it is to-day, without any efficient machinery to ascertain the numbers, and causes of death, without any drainage, without any water supply, without any registration of accredited apothecaries, much less doctors, without, in fact, anything but the barest skeletal beginnings of medical control, Bangkok has all the possibilities of becoming a very volcano of pestilence, and perhaps a fortnight of unusually cold weather, or something equally trivial, will start the eruption.

Sea Voyages for Invalids.—The discussion on "Sea Voyages for Invalids," published in the *Journal of Balneology and Climatology*, January, 1906, provoked a number of opinions as to the advantages and disadvantages of sea travel for invalids. The consensus of opinion, including that of Dr. Robert W. Felkin, who opened the discussion, seemed to be, as a rule, against the treatment. He stated that the principal ailments which precluded a sea voyage are: (*a*) The strength of the patient—if there is too great exhaustion it is better to keep him on land; (*b*) grave dyspepsia; (*c*) hepatic enlargement; (*d*) cardiac dilatation; (*e*) pyrexia or any inflammatory condition; (*f*) any tendency to hæmorrhage; (*g*) epilepsy; (*h*) insanity; (*i*) pregnancy; (*k*) patients suffering from eye diseases; (*l*) any kidney disease; (*m*) phthisis, except, perhaps, in the very first stages, and I think even then such a patient should occupy a deck cabin *alone*." Dr. F. Sandwith's remark that:—"The doctor who sent many patients to sea was generally one who had not done much travelling in bad weather," succeeded best perhaps in summing up the situation. Chloretone was mentioned by Dr. Leonard Williams as the drug which had proved most successful in alleviating sea-sickness.

The *Geographical Journal*, for March, 1906, contains a useful abstract of a paper by Dr. J. Hoffman, in Petermanns *Mittellungen*, 1905, Nos. 4-7, on Minimum Temperature in Tropical Africa. The area dealt with is the south equatorial region, more particularly the high plateaux of East Africa. The author discusses the effect on the minimum of temperature of elevation, distance from the sea, rainfall and winds throughout the year, and attempts to deduce some general laws therefrom. He finds that the minima diminish with distance from the coast, and increase of latitude, but the variation with altitude cannot be stated simply, as the diminution is affected by many disturbing factors.

The facts are different, *e.g.*, for stations on a mountain range, on a plateau, or on the slope of an isolated peak rising from a plain; the general law of diminution for elevation holding good least of all for a mountain region cut up into valleys. Humidity and cloudiness are also disturbing factors as illustrated, for example, that under these circumstances a minimum of 39·2° F. was observed at 2,675 feet, near Rinvenzori, whereas so low a temperature had never been recorded up to 6,230 feet on Kilimanjaro.

The important question as regards agriculture, of the limits of night frosts is also considered and the conclusion arrived at is that, near the equator, there is no good evidence of actual frost at any height under 6,500 feet, though cold nights approaching freezing point are not uncommon.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 ,, ,, 6/-;
200 ,, ,, 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 ,, ,, ,, 11/-;
200 ,, ,, ,, 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

APRIL 16, 1906.

THE DAILY RANGE OF HEAT AND HUMIDITY IN TROPICAL COUNTRIES.

OF the different meterological data that are required for the comparison of climates, there is no one as to which so much misapprehension exists as to that of humidity. The reason of this is to be found in the fact that direct quantitative figures are absolutely useless for comparative purposes, as such figures convey no idea whatever of the dampness or otherwise of a place. Even in the heart of the Sahara, the actual weight of watery vapour present in the air seldom, if ever, is as small as it is in London during a November fog; but in spite of this, the fierce dryness of the desert in June rivals for inconvenience the damp misery of a "London special."

The reason of this is that the amount of water that the air can carry without deposition varies with the temperature, and that it is only when the air approaches saturation that the sensation of damp is conveyed. Under other conditions, watery vapour is as "dry" as any other gas, for our sensations inform us not as to absolute but to relative dampness. Macaulay's schoolboy would probably have been aware of this had he belonged to the present generation; but what is not generally recognised is the corollary that, with the daily changes of temperature, relative humidity is constantly changing from hour to hour, and that consequently observations from different places are in no way comparable unless they are taken at corresponding hours of the day. For strict comparison of places widely differing in latitude, it is not sufficient that they should be taken at the same hour of the day, as owing to the great differences in the length of the daylight hours at different latitudes, observations at the same hour are only exactly comparable at the equinoxes. At all other times of the year equatorial climates are made to appear comparatively too dry in the winter and too moist in the summer, as for comparative purposes, where only one or two observations are taken during each day, it is essential that they be taken, not at the same hour, but at the same interval from sunrise and sunset. Observations such as this, necessitating different times of observation for each month, are, however, almost out of the question in actual practice, and fortunately, within tropical and subtropical limits the day does not differ sufficiently in length to seriously vitiate the comparison of observations taken at fixed hours. But even in stations under the same flag, the hours of observation vary greatly, and nowhere more so than in our British colonies, so that it cannot be too clearly understood that comparisons of relative humidity are usually utterly fallacious unless it be clearly recorded that they are taken at the same hour, or that careful and somewhat difficult corrections be made to compensate for the different times of observations.

In humidities of about one-third of the possible water-holding properties of the air, it happens that a rise of one degree Fahrenheit in temperature corresponds almost exactly with a fall of 1 per cent. of relative humidity, and it is therefore convenient to commence our study of the normal curves of these two climatic factors with an example of a climate of this sort. The number of stations where hourly observations of sufficient duration have been taken is but small, and we are therefore somewhat restricted in our choice; but the case of the climate

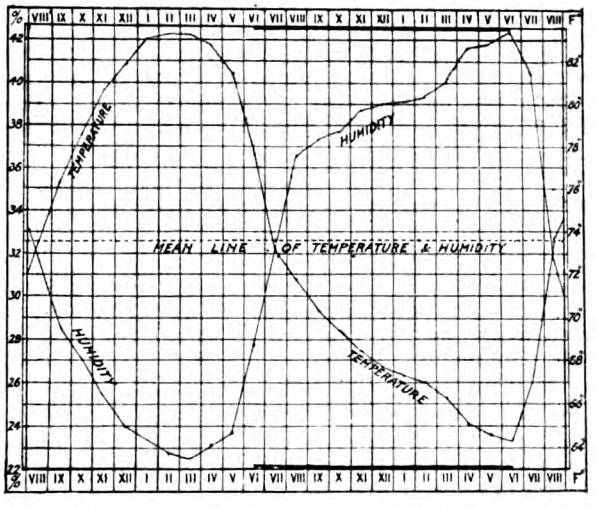


FIG. 1.—Diagram of diurnal variation of temperature and humidity at Pachmari during March. The figures on the left refer to percentage humidity, those on the right to temperature (Fahrenheit). The heavier horizontal border lines indicate the hours of darkness.

of Pachmari, in the Central Provinces of India, for March, which is graphically represented below, will serve sufficiently well for our purpose.

The first point that strikes the eye in examining these curves is their almost perfect symmetry, which is the more remarkable as they are plotted from the data of a single month; and we may be sure that in a term of years the curves would smooth out to perfect regularity. This is, of course, only what is to be expected from the ordinary law of physics, and is merely an expression of the fact that the *absolute* amount of watery vapour in the air can vary but little from hour to hour, save in exceptionally circumstanced localities, such as those influenced by diurnal land and sea breezes.

It will be noticed that both curves start from the mean line about 8 a.m., and leave it in opposite directions. At first very rapidly and then more slowly, till they respectively reach their maximum and minimum points, which in the case of temperature is reached about 2.30 p.m., and of humidity shortly after, at 3 p.m.

From this time the changes are slow until 5 p.m., after which the fall of temperature and rise of humidity are extremely rapid until 8 in the evening, the mean line being crossed about 7 p.m.

From this time the temperature falls and the humidity rises steadily till 6 a.m.; after which, with the rising of the sun, both lines turn steeply back to regain the mean again at 8 a.m. It will also be noticed that while the curves of the heat of the day form bold and fairly symmetrical loops, those of the cooler hours are quite different, the fall of temperature being very slow in comparison with the rapid rise after dawn. Now, 7, 8 and 9 in the morning are very favourite fixed hours for taking meteorological observations, and it will be observed that two observatories placed side by side at Pachmari, one of which observed at 7 a.m., while the other did so at 9, would record relative humidities of 40·5 per cent. and 28·5 per cent. respectively, while the difference between 7 and 8 a.m. is quite sufficient to give an entirely erroneous impression of the comparative dryness of the two really identical places. It might at first sight be thought that a single observation taken about 8 a.m. would give a very close approach to the mean temperature, but a moment's inspection of the curves shows that they are so steep at both of the points where they cut the mean line that a very trifling lack of punctuality would seriously vitiate the results, as the conditions change at these times of the day as much in a few minutes as they do in an hour when approaching the maxima and minima. Many observatories take their observations at 9 a.m., 3 p.m. and 9 p.m., but on this plan two of the three observations are too near the mean to be at all independent of exact punctuality, and the mean of the three will necessarily be much in excess of the true mean.

At Cairo and some other first-class observatories, observations are taken at 6 and 9 a.m., 3 and 6 p.m., and midnight; and such a series gives a close approach to the true mean of the year, but it cannot be trusted in the case of individual months, as a very casual test of the plan brought to light months in which these data yielded results as much as 2·5 per cent. different from their true mean, which is no better than is afforded by the mean of the maximum and minimum humidities alone, without taking any other data into the calculation. On entire years indeed, mean humidities calculated on this latter plan seldom err by more than 1 per cent., so that though for annual figures the plan of five observations may be admitted to give a closer approach to the true mean, its advantages over the simpler method are quite inconsiderable.

But elaborate observations of this sort are only possible in observatories of the first class, and we are probably well within the truth in surmising that the stations where they are taken might be numbered on the fingers for the entire British Colonial empire.

Moreover, unless they be supplemented by separate figures obtained on some simpler plan they are quite as useless for purpose of comparison with the great bulk of stations as those of the humblest observatory with its single part-time observer, from whom at most but two daily observations can be expected. We have already seen that morning and evening observations are undesirable, because at these times of the day the changes are so rapid as to lay them open to many fallacies, not the least of which is that even in sub-tropical regions the varying length of the days will bring about considerable differences in the apparent results of different months.

We are thus reduced to observations taken near the maxima and minima, but one of these occurs at night, and the other in the busiest hour of the day, and so cannot be reasonably expected from part-time observers.

We are reduced, then, to the necessity of employing self-recording instruments; and as thermographs and other continuously recording instruments are expensive, delicate, and troublesome to manipulate, we are practically reduced to the employment of maximum and minimum thermometers which are open to none of the above objections.

In other words, it is proposed to employ wet bulb maximum and minimum thermometers, and to employ these in conjunction with the corresponding dry bulb instruments to calculate the maximum and minimum humidities. The only objection that can be advanced to this proposal is that the wet bulb extremes do not always coincide in time with those of the dry bulb. Now, the principal reason of this is that wet bulb thermometers move more slowly, and therefore have a tendency to lag behind the dry instruments, but the same objection may be taken to all hygrometric observations deduced from these instruments at any possible time or combination of times; and though irregular factors may slightly vitiate the advantages of the proposed plan in fickle climates, such as that of England, an examination of the above and following curves, as well as many others that have been plotted, shows that this source of error cannot be considered as of any practical importance in the case of hot climates. Moreover, in the case of temperate climates the irregular factors of this source of error necessarily have a tendency to correct each other in any at all extended series of observations, even such as a month. Above all, the results of the plan would be strictly comparable, a character entirely wanting in our meteorological returns as at present constituted.

The accidental relations of a change of 1° F. in temperature, corresponding to 1 per cent. of relative humidity is, however, confined to very dry climates.

Under conditions of greater moisture, the percentage of humidity alters much more rapidly than the temperature, as expressed in degrees Fahrenheit; so that at humidities of about 65 per cent. a change of 1° F. corresponds to a change of 2° F., and in ordinary equatorial and insular warm climates, the proportion is even higher, and may reach as high as 2·4 per cent. of humidity to the degree Fahrenheit; though in exceptional cases, as in the almost saturated climates of tropical hills, there appears a tendency for the ratio to fall as saturation is approached.

These relations between changes of temperature and moisture appear to be fairly constant, and are represented by the diagram below (fig. 2).

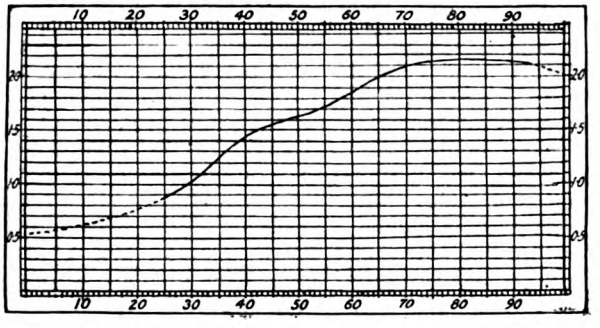

FIG. 2.—Curve illustrating the relation between the ranges of temperature and humidity at varying degrees of atmospheric moisture. The horizontal borders are graduated to percentage humidity, the vertical to the factor by which an alteration of temperature must be multiplied to obtain the corresponding alteration in relative humidity, *e.g.*, the curve cuts the vertical of 30 per cent. at 1·, at which humidity an alteration of 1° F. corresponds to a change of 1 per cent. relative humidity, while at 63 per cent. humidity a change of 1° F. is associated with that of 2 per cent. relative humidity.

The information so afforded is necessarily only approximate, and has been obtained in a purely empirical manner, but is really of practical value, when it is desired to make a comparison of data collected at different hours, the more as the mean temperature does not appear to notably affect the ratio, at any rate within the climatic limits we are considering. On this account it is commonly more convenient in diagrams to plot the changes of humidity on half of the scale of those of temperature, and this plan is adopted in fig. 4, the last of the instances plotted.

Moist air is a much better conductor of heat than dry air, and also obstructs radiation, much heat being absorbed instead of passing through it. Changes of temperature are therefore much less rapid in moist climates, and the diurnal range of temperature much smaller. These differences are graphically illustrated in the contrasted ranges of temperature and humidity of the very dry climate of Jaipur in Rajputana for the months March, April and May, with those of Rangoon in Burmah for the months July, August, and September, though the mean temperatures of the two stations (78·7° F. for Rangoon and 84·1° for Jaipur) during those periods do not differ greatly. The mean humidity of Rangoon, however, during the period in question is 92·7 per cent., while that of Jaipur is but 33·5 per cent.

There are, however, other factors at work in the production of uniformity of climate than can be gauged by hygrometers installed at or near the ground level,

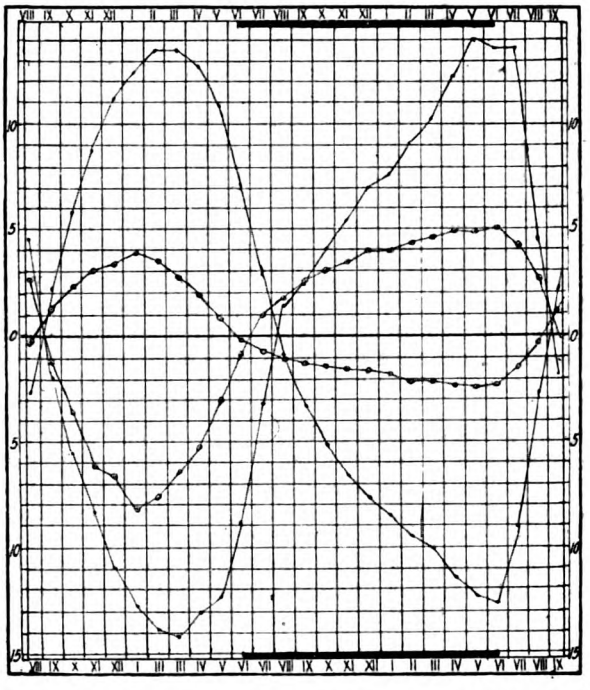

FIG. 3.—Graphic representation of the hot season in Jaipur, contrasted with the wet season in Rangoon. As in the last figure, temperature (Fahrenheit) and percentage humidity are plotted on the same scale. The lines with ringed nodes refer to Rangoon.

the principal of these being the amount of cloud which is determined by the hygrometric conditions not of the lower, but of the upper regions of the atmosphere which do not, by any means, necessarily correspond.

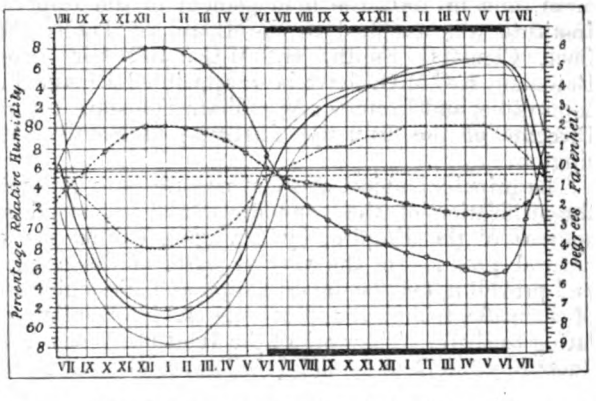

FIG. 4.—The above curves show the relation between temperature and relative humidity for a mean day calculated from hourly observation throughout the year. The heavy lines are the means of three years' observation at Mauritius, the dotted the same for Hong Kong. In each case the curves of temperature are indicated by the nodes being marked by small circles. The curves of temperature are plotted at 2° F. for each 1 per cent. relative humidity. The lighter lined curves are those of December and June for Mauritius for relative humidity.

The finely divided particles of water that form clouds and fogs are far less transparent and diathermic even than moist air; and the former not only greatly tempers the heat of the day, but also form a protective roof, which prevents loss of heat by radiation at night.

These differences are well shown in fig. 4, in which the diurnal changes for the means of the year are plotted for—the islands of Mauritius and Hong Kong respectively. An even more striking contrast might have been afforded by the extremely uniform climate of Batavia, but there the daily variation is so small that on the scale the diagrams are reproduced, the lines would be inconveniently near the mean lines for exact inspection. The mean humidities of the two islands, it will be seen, differ only by less than 1 per cent., and their mean temperatures sufficiently approach to each other for practical comparison. It will be thus seen that provided we are furnished with the maximum and minimum of temperature and humidity, and the average amount of cloud, we can form a very close estimate of the character of a climate and of its effect on the human system—apart from endemic diseases which usually depend on the quite different question of the geographical distribution of parasites, though these in their turn are necessarily much influenced by climatological conditions which thus, after all, are mainly responsible for the healthiness or sickliness of any given locality.

G. M. Giles.

THE IMPERIAL INSTITUTE.

The fourth number of the third volume of the "Bulletin" of the Imperial Institute, just issued, gives a short account of the present position and the work of what promises to be an eminently useful institution, when once it is in full working order. The Imperial Institute was founded as a national memorial of the Jubilee of Queen Victoria, and opened by Her Majesty in May, 1893. In 1900 the building became the property of the British Government, and in 1902 the management of the Imperial Institute was assigned to the Board of Trade. Sir Cecil Clementi Smith, G.C.M.G., and Sir Alfred Bateman, K.C.M.G., have been appointed a managing committee, and Professor Wyndham Dunstan, F.R.S., Director of the Imperial Institute at South Kensington.

The principal object of the Institute is to promote the utilisation of the commercial and industrial resources of the Empire, by arranging exhibitions of natural products of the various parts of the empire, and providing for the investigation and dissemination of scientific, technical and commercial information relating to them. The work of the Institute is now conducted by the Commercial Intelligence Branch of the Board of Trade, which is located at 73, Basinghall Street, London, E.C., and by the Emigrants' Information Office in Westminster.

Thirty-eight colonies and dependencies have their economic products arranged on a geographical system in the galleries of the Institute. A Bureau of Information has been opened to facilitate the supply of general information and the distribution of literature. A Scientific and Technical Department, consisting of well-appointed laboratories, deals with the investigation of the new or the imperfectly known products of the colonies and of India, with a view to their utilisation in commerce; and British Consuls are encouraged to transmit natural products of the countries to which they are appointed. In the Institute is an excellent library as well as reading rooms, and three specially appointed rooms termed colonial conference rooms. The Cowasjee Jehanghier Hall is used in common by the Institute, the India Office and the London University for lectures, meetings and conferences.

Nor does the work of the Imperial Institute end with these, for the British Women's Emigration Association and the Colonial Nursing Association (Room 5) have had offices portioned off for their use and occupation. The "Quarterly Bulletin of the Imperial Institute" is a valuable publication, and not only announces the work being carried on at the Institute, but supplies technical information concerning many of the less known natural products of the British Colonies and of India. In the volume just published we find reports on "Cotton from the Federated Malay States," "Fibre of Asclepices Semilunata from Uganda," "Lokesi" fibre from North-Western Rhodesia, "Black Damar Resin from Assam," and several other articles of high economic value.

The "Bulletin," price 1s., is obtainable at Messrs. Eyre and Spottiswoode's, Fleet Street; Messrs. G Street and Co., Cornhill; or at the Imperial Institute, South Kensington.

SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS, NEW YORK, SEPTEMBER, 1907.

President: Dr. James C. White, Boston, U.S.A.

To the Editor of the Journal of Tropical Medicine.

Dear Sir,—The Organising Committee of the Sixth International Dermatological Congress to be held in New York, September, 1907, has selected as one of its topics for discussion Tropical Diseases of the Skin. Can you, perhaps, suggest someone in Great Britain or your colonies to report on the subject from a dermatological standpoint?

Very truly yours,
John A. Fordyce, M.D.

80, West 40th Street, New York,
March 8th, 1906.

[Will those intending to take part in the discussions on Tropical Diseases of the Skin at New York, in September, kindly communicate with Dr. Fordyce direct?—Ed. *J. T. M.*]

Abstract.

CONDITIONS AFFECTING THE LOCATION OF MISSIONARIES OR THEIR RETURN AFTER FURLOUGH.[1]

By C. F. Harford, M.D.

Principal, Livingstone College, Leyton, London, E.

There are few questions more difficult to decide than those which relate to the influence of climate on the health of individuals. This is even the case with our own little island; and when we are called upon to

[1] Read before the Medical Officers of Missionary Societies, January, 1906.

advise those who may be called upon to take up work in distant regions of the world, the complexity of the problem is very largely increased from the fact that uniformity of climate does not exist throughout any large territory in any part of the world.

In the selection of suitable candidates for service in the mission field, although we may not all be agreed as to the exact points which should lead to disqualification, we are at one in requiring that candidates for foreign service should be physically sound.

It must be remembered, however, that the mission field is a wide one, and there are candidates who would be totally unfitted for work in some regions who might be able to do useful service in other parts, so that we need to use great discrimination in the selection of countries to which each Missionary may be permitted to go.

It will probably be best to adopt a geographical order, and to note the prominent characteristics of those countries to which Missionaries are most commonly sent, and in so doing we may select first the continent of Africa, which presents some of the greatest difficulties of climate, though parts of it may be included under the healthy regions of the world. It may be considered in five sections: (*a*) West Central Africa, including Senegal, and Niger and Congo basins; (*b*) East Central Africa, including Upper Nile districts and Zambesi basin; (*c*) highlands of Central Africa; (*d*) South Africa; (*e*) North Africa.

(*a*) *West Africa.* — West Africa has the unenviable reputation of being the most unhealthy part of the world, and by West Africa we mean the coast districts extending from the Senegal to the Congo, and including the country drained by these two rivers and the Niger. Probably the occurrence of very grave forms of malaria and the prevalence of blackwater fever account for much of the unhealthiness of the climate, but the houses are not, as a rule, carefully constructed, and often are built in close proximity to insanitary native huts; the food supply is in few instances well developed; there are no health resorts to which Europeans can readily go nearer than the Canary Islands, and there are little opportunities for exercise and recreation.

(*b*) The *East African* districts present very similar conditions to those found in West Africa, but the form of malaria is perhaps not quite so malignant, and there are better opportunities for obtaining change for recruiting health.

(*c*) *Highlands of Central Africa.*—Certain parts of Central Africa have proved to be much more healthy than the coast districts. This is the case in Uganda, where European Missionaries have been at work, and very few deaths from climatic diseases have taken place, and very few have been invalided home. In the high plateaux of eastern equatorial Africa even better health conditions are to be met with, and some of these appear to be quite suitable for European colonisation. The same sort of conditions are to be met with in the Shire Highlands in British Central Africa.

(*d*) The climate of South Africa is, in many ways, better than England, and in some parts would suit constitutions to whom the European winter is trying; malaria and bowel disorders occur in certain districts, but these may be largely prevented with care.

(*e*) *North Africa* possesses an ideal winter climate, but the summer months are exceedingly hot. If it is possible to take a holiday in a cooler region during the months of July to September, the climate may be suitable for many who could not work in a tropical climate.

Palestine and Syria.—What has been said about North Africa applies to a certain extent to these parts, but it should be remembered that malaria is very prevalent in Palestine at certain seasons of the year, and owing to defective sanitation in the chief cities, there is great risk of contamination of the water and food supply, and thus bowel disorders are frequent, and epidemics of cholera are not unknown.

Arabia, including Turkish Arabia, possesses a very hot climate, and in some seasons it is intensely hot, whilst here, again, sanitation is almost unknown.

Persia possesses a fairly temperate climate, and, apart from bowel disorders, there is very little climatic disease.

India.—The houses in India are more generally suited to the climate, whilst there is usually a good food supply, and good sanatoria can be found in the principal hill stations, which can be reached by a good railway system.

South India, with which we may include Bombay and the Central Provinces of India, is distinctly tropical; the east coast is more trying than the west, and there is more malaria in the east.

North India possesses a fairly temperate winter climate, and many Europeans pay visits to India during this season with very slight risks to health.

Apart from the definite hill stations, it is probably, true to say that the United Provinces possess the best climate. The Punjab, Sind and Rajputana probably rank next in point of view of healthiness, though the heat here is often most intense. Probably the most unhealthy is Bengal.

Burmah may be classed with Bengal on the point of view of climate, whilst the health conditions of Siam and the Straits Settlements may be compared with those of South India.

China possesses even a greater range of climate than India, but the sanitary conditions are bad, and there is, therefore, a tendency to bowel disorders. There is also a special strain on the nervous system in China; and Missionaries to China should have no tendency to mental or nervous disorder, either hereditary or acquired.

South China is distinctly malarious, and might be classed with Bengal. North China, on the other hand, has an intensely cold season, and is fairly free from any climatic diseases.

Japan.—The climate of Japan cannot be regarded as an unhealthy one, but there is one difficulty which must always be kept in view in selecting workers for Japan, viz., the great tendency to a curious form of headache, which is often spoken of as "Japan head."

America.—In the American continent our chief attention must be directed to the tropical regions which are to be found in Central America and to the north of South America. The health conditions in many parts are exceedingly unhealthy, and may be compared with East Africa, though the prevalence of

yellow fever must be taken into account, which does not occur in East Africa.

Tropical Islands.—Each of the important tropical islands has some special features of its own, and particularly with reference to the distribution of malaria. Naming the most important, we may mention Madagascar, Ceylon, East Indian Islands, and the West Indies. These are usually more healthy than similar regions on the continent.

Cold Climates.—There appears to be little climatic disease in cold regions, such as in the northern districts of North America, but there are great hardships to be endured, which require considerable powers of endurance.

The Return of Missionaries after Furlough.—There are many causes which may prevent the return of Missionaries to different parts of the field.

Individuals who suffer from persistent attacks of malignant malarial fever should be regarded as unsuitable for malarial climates. Repeated attacks of blackwater fever should be regarded as a disqualification, and one particularly severe attack may, however, be regarded as equivalent to several slight attacks.

Continued diarrhœa is one of the most serious conditions which affect the prospects of useful service in the Tropics, and unless a permanent and satisfactory cure can be obtained, there must be no thought of return to the mission field.

Persistent nerve troubles, such as sleeplessness, headache, or any tendency to mental weakness, are signs of danger which must not be disregarded, especially as they are likely to be accentuated by further residence in the Tropics.

Other cases will be found in which there appears to be some particular idiosyncrasy which renders the individual unsuitable for work in one country or location, and yet which might not debar him from work in another climate. A reference to some of the climatic conditions of the different countries may help in finding the most suitable location.

Review.

J. Courmont, of Lyons, on the "Atmosphere," and C. Lesieur, of Lyons, on "Climatology," in a Treatise on Hygiene, published by P. Brouardel and E. Mosney, T. 1., fascic. i., pp. 124. Paris, J. B. Baillière. 1906.

The characters of the atmosphere are studied from the standpoint of public health. Ten pages are devoted to its chemical and twenty-three to its physical properties; the characters of free and confined air being separately considered. Another ten pages are given to the question of inorganic dust and the methods of dealing with dust nuisances, after which living organic dust—the bacteriology of the air, in fact—is considered in the final thirteen pages. The variation according to season and altitude in these living forms of dust, the transmission of diseases through the agency of the air, and the natural means of purification by time, drying, and by the sun's light, are all briefly considered, so that the article is one which treats systematically of a subject which has hitherto been but scantily dealt with in text-books.

M. Leisieur's article on climatology is necessarily too brief to include more than a bare sketch of his subject, and so wisely devotes most attention to temperate European climates, but some notice of hot and cold climates is also included, and the last five pages are devoted to the question of adaptation to climate.

Correspondence.

THE REVIEW OF HUGGARD'S HANDBOOK OF CLIMATIC TREATMENT.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

SIRS,—Not until two or three days ago did I see your issue of February 15th, in which you courteously inserted my letter criticising your Reviewer's notice of my book. But by printers' errors in the placing and in the omitting of quotation marks, I am made to adopt the Reviewer's standpoint.

In these circumstances I beg permission once more, and finally, so far as I am concerned, to place the point at issue before your readers.

According to my exposition the comparative coldness of the upper layers of the atmosphere is mainly due to the physical laws of the expansion of gases, a body of doctrine as fundamental in modern meteorology as is the doctrine of gravitation in astronomy. But according to your Reviewer "this law explains only the rather exceptional case of uphill winds." An exactly equivalent criticism in astronomy would be that the law of gravitation explains only the fall of apples. To the Reviewer's mind the true reason of the comparative coldness of the upper layers of the atmosphere is "the universal operation of the law of selective absorption."

In reply to my criticism your Reviewer quotes the first two paragraphs from Hann's Exposition of the Causes of the Vertical Decrease of Temperature, in which Hann points out "that the storage of heat at the bottom of the atmosphere results from the peculiar behaviour of this atmosphere towards solar radiation. This process has been called *selective absorption.*"

That the special storage of heat in the lower layers of the atmosphere accounts for the comparative coldness of the upper layers may be claimed by your Reviewer as a discovery of his own. At any rate this explanation does not appear to have struck Hann, who, a page or two after your Reviewer's quotation (*Handbuch der Klimatologie*, 2nd ed., 1897, vol. i., p. 264), continues as follows:—

"Therefore the general law holds good: Ascending masses of air cool at the rate of 1° C. for each 100 metres of elevation, so long as no condensation of water vapour takes place; conversely, descending masses of air become warm at the same rate.

"If we imagine the air masses of the atmosphere so thoroughly mixed in a vertical direction that every particle of air had several times passed through the whole height of the atmosphere, the fall of temperature would then be found to be 1° C. for each 100 metres of height. At this rate of decrease of temperature a rising or a falling mass of air would, at each level, encounter its own temperature, that is to say, it would in each level be in equilibrium, having no tendency to rise or to fall. This is the condition of indifferent (convective) equilibrium."

That the actual rate of cooling in the lower layers of the atmosphere is much less rapid than theory would lead us to expect is explained partly by selective absorption and partly by the heat set free through the condensation of moisture.

In his *Lehrbuch der Meteorologie*, 1901, p. 161, Hann says: "The more recent balloon journeys have shown in fact at heights over 6 to 8 kilometres a fall in temperature of 0·8-·9° C. per 100 metres; and this proves that at

Bale, Sons and Danielsson, London.

these heights vertical movements of the air must be very frequent, since they almost determine the temperature of these high layers.

Thanking you in advance.

I have the honour to be, Sirs,
Your obedient servant,
WILLIAM R. HUGGARD.

Davos-Platz, March 23rd, 1906.

[At the urgent request of Dr. Huggard we departed from the general rule of all publications, scientific or otherwise, that a reviewer's comments are privileged.

At first sight this rule might appear to be unfair to the reviewed, but it is obvious that but for its existence, either reviewing would fall to the level of uniform inane compliment, or much of the space of periodicals would be occupied with discussions interesting only to the combatants concerned. We therefore propose to adhere rigidly in the future to the wholesome general rule, and if any author is not prepared to accept our review of his work, for what it may be worth there is no need for him to forward it for review.

The present instance is a good case in point, as it has involved printing long extracts from a standard work accessible to everyone. Both reviewed and reviewer, of course, are perfectly aware of the rudimentary fact that gases get hot when compressed, and cool when they expand, but if this determined the temperature gradient for different elevations the fall of temperature in ascending would be much more rapid than it is, and the actual usual gradient is determined by the action of selective absorption. We have equally no doubt that Dr. Huggard thoroughly understands this, but he has failed to make it clear in the book reviewed, in which "selective absorption" is not even mentioned in the index. It is not enough, however, for an author to understand his subject, as he fails in his object unless he succeeds in making others do so. This discussion must now be closed.—ED. *J. T. M.*]

PLAGUE AND FLEAS.

THE Indian Plague Commission are said to have definitely proved that rat fleas are the normal vehicles of infection in animals, and probably in man. This has been arrived at by shewing that animals protected by fine wire gauze remain immune in plague-infected buildings, while unguarded controls contract the disease in large numbers. Although Ogata as far back as 1897 shewed that the titurated fleas of rats were infective, the theory of insect transmission has been generally "pooh-poohed," and much of the credit of bringing the matter again to the fore is undoubtedly due to Capt. Glen Liston, I.M.S., whose paper in the *Indian Medical Gazette*, of February, 1905, may certainly be considered the new starting point of the now triumphant theory.

Notes and News.

METEOROLOGICAL stations are to be instituted under the Indian Meteorological Department at Pharo and Gyantse in Tibet, and as these are our only present stations beyond the Himalayan watershed, the gain to meteorological science can hardly fail to be of the first importance, especially in connection with the supposed relationship between the snowfall of Central Asia and the intensity of the south-west monsoon.

MR. HUGH CLEMENTS' FORECAST FOR THE SOUTH-WEST MONSOON OF 1906.

Omitting a number of illustrations of the infallibility of his methods based on the weather in Bombay, we reproduce from the columns of our contemporary, the Allahabad *Pioneer*, the following letter on the forthcoming monsoon:—

"The south-west Indian monsoon is not a magnified land and sea breeze, as stated in all pseudo-scientific works, but is caused by the tidal action of the moon and the sun forming depressions to the north of India, towards which the air from the Indian Ocean is drawn by the great inequality in the barometric pressure.

"From the position of the moon and the sun at any moment I am enabled to localise the depressed area all over the world, and thus predict unsettled and wet weather. For each place there are certain lunar and solar celestial positions correlated with periods of depression and rainfall.

* * * *

"In accordance with my calculations of the height of the barometer and rainfall for each day, may I venture to predict that the south-west monsoon will break on May 16th, 1906, and continue off and on till August 13th? There will be some rain again after the first week in September and at the end of August.

"It will be windy round the British coasts on January 3rd, 11th, 22nd, and 29th, 1906.

"*A*. My prediction of mild and cold periods from November 21st has been amply verified.

"*B*. The *Daily News* of December 21st, 1905, contained my Christmas forecast, and proved accurate in every detail.

"HUGH CLEMENTS.

"Newton House, Burry Road,
"Dulwich, S.E.,
"*December 31st*, 1905."

The above extracts may be of interest to such of our readers as reside within the limits influenced by the south-west monsoon, especially as by the time this issue reaches India the performance of the monsoon of 1906 will be "just agoing to begin," and they will be able to compare the actual facts of Nature with the predictions of the prophet. The objections held by ordinary students of meteorological science to Mr. Clements' theories are sufficiently obvious, and are based on the facts that in the first place, although an atmospheric tide undoubtedly exists, the wave so produced is so feeble that it can only with difficulty be recognised in barometric records; and again, it is difficult to see how a series of phenomena regularly recurring every lunar month can account for a seasonal phenomena lasting some five or six of these periods. Oceanic tides can be foretold with a mathematical certainty which was recognised in proverbial folk-lore long before the facts had been reduced to tabular statement; but quite the reverse is the case with the south-west monsoon, which has hitherto defied the efforts of the scientific weather forcaster in a manner that has led the Indian public to regard his predictions with rather more amusement than confidence.

Of course, the official meteorologists would be the

first to admit the inadequacy of our present knowledge and means; but even if Mr. Clements chances to hit the mark on the present occasion, it would require several years of success to convince those who have most deeply studied the question to look upon a successful guess as other than a coincidence.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Journ. Roy. Met. Society," 1906, p. 21.

GENERAL FEATURES OF THE PRESSURE AND WIND CONDITIONS OVER THE TRADES-MONSOON AREA.

Dallas, W. L., epitomises the results of ten years observations from ships' logs, and land stations, recently collated by the Indian Meteorological Department, within an area of 32° N. to 12° S. and 40°-140° E.

These show that, taking the whole area, pressure is highest in January and lowest in July, while the wind is strongest in the latter month; but shows, unlike the pressure, not a single maximum in January, but double minima about March and October.

The apparent discrepancy is due to the undue preponderance of the northern latitudes, and the contrast in the distribution of sea and land of the belts north and south of the line. Even, however, if two 4° belts N. and S. of the equator be taken; the double oscillation, corresponding to the position of the vertical sun is very ill-defined, and moreover, in both zones, there occurs a minimum in April but there is none to correspond with it in October, nor do the pressure maxima occur at the solstices.

The pressure changes from month to month are much less symmetrical than might be expected. They are smallest at the two solstices, when the sun remains practically stationary over lat. 21° for two months, and largest between May to June and September to October, as a result of the large temperature changes then occurring over the large land surfaces of Southern Asia.

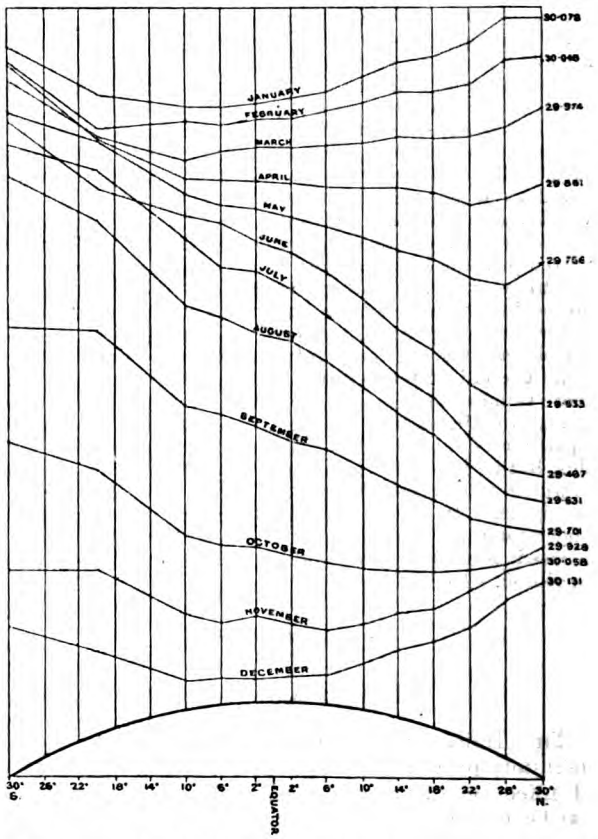
The distribution of pressure in each month in the included area is then discussed, but these are best studied in the appended graphic representation.

It will be observed that the pressure changes lag a great deal behind the sun. In spring and autumn the curves are saucer-shaped, the lowest pressures being between the equator and 10 S°., and as a result, the winds north of this area have a marked northerly component, and those south of it a southerly; but in April the distribution changes, and there comes into existence a steady decrease of pressure from lat. 30° S. to 22° N., while the high pressure area in 30° N. is very slight and unimportant. From May to August these changes are maintained and intensified, there being a steady gradient from 30° S. to 30° N., which is at its steepest in July, when it amounts to nearly three-quarters of an inch of mercury, but there is a smaller second maximum of a quarter of an inch in December, with interposed minima in February and November, when the range of gradient is no more than 1·7 inch. The calms of these latter months and the strong winds of February are easily understood by following the curves for each month.

The most important point in the paper, however, is that the author quite rejects the old theory that dominates many of the past official memoirs of the Indian Meteorological Department.

These were to the effect that the monsoon current is due to an impulse in one spot, like a jet of steam issuing from a closed reservoir. For example, in a *Memorandum*, written in 1891, these views are stated as follows:—

"Hence the advance or extension (or burst of the monsoon) takes place from South to North, and therefore cannot be explained as a mere indraught to a hot area. The phenomena rather indicates that there is a vast resistance to be overcome, and that when this is effected by a force from the rear, the massive current moves forward and invades India."



By means of a table showing the barometric gradients from zone to zone, and the mean wind force, the author shows that the observations discussed afford no evidence of any such "tempestuous obstacle overcoming onslaught," and that "a general agreement between the pressure differences and the mean force of the wind obtains throughout the whole area and throughout the whole monsoon period, and the velocity and strength of the winds of the circulation appears to be regulated by the ordinary rules of the differences of barometric gradient, and not, at any time, by a single impulse imported to the rear of the aerial current."

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the JOURNAL OF TROPICAL MEDICINE should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communications.

NOTE ON THE TINEA IMBRICATA IN BRAZIL.

By Ulysses Paranhos, M.D.
Assistant in the Pasteur Institute; Physician to the Charity Hospital; and
Caramurie Paes Leme, M.D.
Director of the Laboratory of the Chemical Institute of São Paulo.

The first cases of Tinea imbricata recognised in Brazil were observed by one of us during a scientific excursion ordered by the Government of São Paulo in Brazil. The first case which, by its evident symptomatology, induced us to make the diagnosis of Tinea imbricata was observed in a native of the Carajas tribe inhabiting one of the islands of the River Araguaya in the State of Goyaz.

Among the Carajás Tinea imbricata is very common. They call it "roôro," which, in their language, means "the flying disease," because they think that hostile tribes blow it in the direction of their huts to cause them harm.

The natives of Brazil generally employ for the cure of this illness the bark of the root of *pinjossara*, which is no other than the plant called *Ocalia perdiceps* of Baill.

One of us was present at the moment of this application for the treatment of the Tinea imbricata among the indigenes, which, on account of its great originality, deserves to be mentioned.

The bark of the root of the *Ocalia perdiceps* is placed in maceration in cold water. On the following day the patient undergoes the application of this medicine, which consists in friction over the whole body with the macerated bark, after which the patient is exposed during half an hour to the action of the sun's rays, and washed afterwards in cold running water, his skin being then rubbed all over with the ashes of the same plant.

The consequences of this treatment are not long in appearing; the skin becomes reddish, being formerly of a bronze colour; the patient becomes agitated, the temperature rises, and sometimes delirium is observed, which often reaches frightful proportions. This state of things lasts from four to six hours. Sleep comes on, and on the following day the patient awakes quite calm, his general condition is good, and the appearance of his skin visibly modified, the large scales fall off, a slight glossy scaling being then observed.

On the third day after this application the same treatment is repeated, but then the reaction of the organism is weaker.

The treatment is thus continued every three days till the complete recovery of the patient. The reaction of the patient always preserves an inverse proportion to the number of applications.

The positive result of this native treatment, though empiric and excessively violent, is undeniable. The treatment of the native Curicy, the first patient whom we observed and a typical case of Tinea imbricata, proves it thoroughly.

Submitting himself to the indigenous treatment, he recovered in our presence from his illness, which did not repeat itself, as the man accompanied our scientific excursion as far as the State of Para, returning in our company to São Paulo without the least sign of reappearance of his dermatosis.

Tinea imbricata exists in Brazil, as we have observed personally, in the States of Goyaz, Matto Grosso, Minas Geraes, and São Paulo.

In the State of Goyaz it rages along the banks of the River Araguaya; in Minas Geraes it exists in the city of Uberaba and its neighbourhood, and in Matto Grosso among the natives on the left bank of the Araguaya.

In the State of São Paulo, where we have better observed it, Tinea imbricata is found on the banks of the River Pardo in Yardinopolis, Sarandy, Visconde, Coronel Orlando, and in the populous city of Batalaes.

Tinea imbricata in Brazil attacks every race. We had opportunities of observing it in individuals of the yellow race, in natives, among the white people, and negroes. Age and sex have no influence whatever upon it. Among our observations cases occurred at the ages between 12 and 50, and the prevalence in either sex is not remarkable.

Social position presents no difference in liability; we have observed the disease in individuals belonging to the lowest class of society, but, on the other hand, we have also seen patients who belonged to the highest ranks, living with all comfort and having the best hygienic conditions.

The disease in Brazil presents itself in the classical manner so accurately described by Sir Patrick Manson in his valuable works on the subject. The disposition of the scales of the skin as a collar, their position resembling that of the tiles on a roof, is quite accurate.

On examining our patients we have always found the parasite described by Tribondeau. For the recognition of the parasite the following process may be employed.

The scales of Tinea imbricata are treated by alcohol at 40° for five minutes, and afterwards with sulphuric ether in a test tube, which should be shaken several times. After having washed the scales with sulphuric ether, treat them with a solution of potasium in distilled water in the proportion of 10 per cent., keeping them in that solution until they are disintegrated.

The scales are then washed several times with distilled water, being left in that liquid for some time to entirely free them from the excess of potassium.

After this nothing more is needed except to spread the scale on a slide, which, under the microscope, presents the *leptophyton* much more transparent and hyaline than the cellular elements. The scale being separated by the process we have described, and the preparation being fixed *a calore*, we can stain it.

The colouring substances employed are any of the aniline stains.

After having coloured the preparation, we wash it with alcohol and distilled water, examining it immediately with the microscope. One of us, in the researches made in the Pasteur Institute of São Paulo, obtained good results with the method of double colouring advised by Jeanselme. Having fixed the

scales of the Tinea imbricata by ethylic alcohol and crystallisable acetic acid, the preparation being free from all greasy substance, is plunged for twenty seconds in a solution of 1 in 100 of eosine orange, and afterwards discoloured by means of a few drops of alcohol at 60° ; the preparation is then plunged for one minute in an aqueous solution of toluidin blue of 1 in 100 and discoloured once more by means of alcohol till the scale gets a clear colouring, after which the preparation is clarified by means of xylol and examined microscopically.

On the specimens coloured by the Jeanselme process one can see the mycelium filaments of the parasites clearly stained in dark blue on the *epidermic* cellular elements, coloured yellowish-red.

Superior to the method of Jeanselme, just described, is the following, mentioned by one of us in the JOURNAL OF TROPICAL MEDICINE, of December, 1905.

This method consists in washing the suspected scale in winter-green essence and Roux mixture; in its disassociation in an ammoniacal solution of 30 per cent., and its colouring by means of lithined aniline blue prepared by a special process. The preparations obtained by this method have a rare precision and show the presence of the parasites, even if these are in minute numbers. They are superior to the methods of colouring in toluidin blue (Jeanselme), or eosined alcohol (Besson), or vesuvine (Trebondeau) and safranine (F. Noe).

In our researches we have always observed, as already stated, the parasite of Trebondeau. The constituent elements are ramified and in great number; each one of them is formed of cubic or rectangular articulations of various sizes. Where the ramifications can be descried the *mycelium* elements present a single body resembling the letter T or Y.

We have investigated with the greatest care to ascertain the starting point of the Tinea imbricata in Brazil, but, unfortunately, all our researches have been failures. It is a current opinion among people inhabiting the infested localities that the Tinea imbricata is derived from water, and shows itself in persons who bathe in the rivers. All that is but a supposition ; it is, however, convenient to observe that the disease has its principal centres in villages situated on the banks of rivers.

One of us has devoted himself to investigations so as to know how far the popular idea regarding the diffusing of the Tinea imbricata through river bathing is true, but nothing has been proved up to the present respecting the subject.

Tinea imbricata is, in our opinion, increasing in Brazil. The fact of its being unknown up to a short time ago denotes it was rare in past periods. It used to attack only the natives, or persons inhabiting those places where physicians were not to be found who were acquainted with tropical dermatology, and who did not make the true diagnosis of the illness. Actually it is quite different, because the disease exists in the populous centres where its greater diffusion is readily understood.

We have tried, on our patients suffering from Tinea imbricata, most of the forms of treatment advised.

We have obtained good results by the application of wet boric compresses, followed by friction with black soap and the use of Goa powder, advised by Branel.

The application of an iodine liniment recommended by Patrick Manson has benefited some patients ; but what has given the best results, in our cases, is the bark of *Ocalia Perdiceps* adopted in the indigenous method.

The general lines of our method are: (1) A general tepid bath with an alkaline solution of one kilogramme of sodium acid carbonate diluted in twenty litres of water. (2) A lotion with the following mixture: Bark of *Ocalia perdiceps*, 50 grammes; glacial acetic acid, 15 grammes; glycerinated water (10 per cent.), 985 grammes; let the whole macerate during two days and then filter. We employ, before making use of this medicine, an alkaline solution to soften the scales and thus facilitate the introduction of the parasiticide medicine to the cellular elements. During this treatment we recommend to the patient a liberal regimen. We add also to this, tonic remedies such as iron, arsenic and strychnine. With this treatment the results obtained are quite encouraging.

MOSQUITO NOTES.

By Lieut.-Colonel G. M. GILES, I.M.S. (Rtd.).

I.—NOTE ON A SMALL COLLECTION OF MOSQUITOES FROM BARHAIN IN NORTHERN ARABIA (SHORES OF PERSIAN GULF).

IT is a curious coincidence that an incidental remark on the scantiness of our knowledge of the mosquitoes of the Arabian peninsula in our last issue had hardly gone to the press, when I received from Dr. A. Bennett one of my collecting boxes with a small collection of mosquitoes from the Island of Barhain.

Unfortunately, too many specimens had been crowded into the box, so that some have suffered a good deal in transit, and it is possible that it may include more species than those enumerated below.

It includes only one specimen of the Anophelinæ, a female *Nyssorhynchus metaboles* (Theobald), rather darker than most of the specimens in the British Museum collection, but this is probably the result of rubbing.

There are a number of specimens of a Mansonia, which represent, I fear, a new species.

Of the ten specimens, eight are males and two females.

Mansonia Arabica, sp. n.—Wings unspotted, but brindled ; clothed with large broad scales, many having the characteristic "bracket" form ; these are mingled white and black, the former largely preponderating; fringe scales entirely white.

Thorax dark brown grounded, clothed with white ferruginous and almost black curved scales, which very probably produce a definite ornamentation which appears to reproduce the two pale stripes of *Mansonia dorsalis* (Meig.).

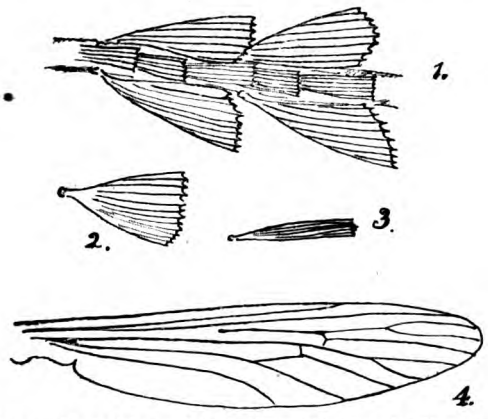
Abdomen generally pale, clothed with a mixture of white, with a few ferruginous scales, the former form-

ing an almost pure white median line, while the latter are mainly confined to the sides. In addition, there are on all but the last segments a pair of L-shaped dark brown spots, the horizontal limbs of which form an apical dark border to the segments, interrupted by the median white line.

Legs brindled, with black, white, and ferruginous scales, giving a generally rather dark effect, with snowy knee spots, and three fairly broad, articular, ferruginous bands on the tarsi (rather variable).

Proboscis dark at the tip and absolute base, and quite pale in the middle, but still not definitely banded.

Head mainly covered with white, forked scales. Antennæ of ♂ ferruginous, of ♀ with almost white plumes. Palpi of ♂ almost white, with darker spots



Mansonia arabica. (1) Portion of 1st longitudinal vein. (2) A broad scale from one of the hinder veins. (3) Lateral scale from anterior fork. (4) Venation.

at the joints and in middle of the long second joint; of ♀, dark brown. Scutellum with white and ferruginous scales; pleura ferruginous, with some white tufts; venter mainly white scaled; sides of abdomen densely fringed with long brown hairs. A fairly large mosquito.

The female has a median, ferruginous abdominal stripe, and the L-shaped spots so large as to be almost continuous laterally, and in both the marking is generally darker than in the male.

In Mr. Theobald's classification I conclude that this species would be placed as a *Grabhamia*, as it is strikingly like our English species *dorsalis*, which is included by Mr. Theobald in that genus. In the ♀ the resemblance is specially close. I confess, however, that I am unable to distinguish the limitations of *Grabhamia*, as the distinction between it and his *Tæniorrhynchus* on the one hand, and *Mansonia* on the other, do not appear to be quite apparent.

The genus *Mansonia*, if not too rigidly defined, is quite a natural one; and as regards the wing, the definition I should prefer would be that the veins should be prominently, but not necessarily, entirely clothed with large broad scales. This would admit of the inclusion of a considerable number of species, such as *fasciolatus*, which Mr. Theobald places in *Tæniorrhynchus*. The asymmetry of the so-called bracket scales is in most cases more apparent than real, and is more commonly an effect of perspective. It is erroneous, too, to assert that in any *Mansonia* there are no median scales, as stated in Mr. Theobald's definition of his genus. Unrubbed specimens must, of course, be selected, but what is actually the case is that in the more typical species the median as well as the lateral scales have assumed the peculiar broad form.

In the present species this is only commencing, though when separate and flattened out, the median scales are considerably wider than they appear in the *camera lucida* outline of the figure. Another character of the genus is that the species are brindled, with mixed scales of contrasting colours, not only on the wings, but more or less over the entire body, and especially on the legs.

A somewhat striking character of the venation of the present species is the exceptional shortness of both the fork-cells.

The two remaining species included in the collection are almost cosmopolitan, for the warmer parts of the world, being:—

(2) *Stegomyia fasciata*, Fabr. Ten specimens, all but two of which are females.

(3) *Culex fatigans*, Wied. Twelve specimens, eight of which are females and four males.

II.—Dr. Adolf Eysell kindly sends me a reprint of the forty-ninth report of the Natural History Clubs of Cassell, entitled, "Sind die, Culiciden eine Familie?" (Are the *Culicidæ* a Single Family?). He first takes up the consideration of the genera *Corethra* and *Mochloryx*, which are now usually placed as a subfamily (the *Corethrinæ*) of the *Culicidiæ*, and gives excellent reasons for deprecating their inclusion with the true gnats, with which probably most naturalists who have studied these insects will agree. It may be remarked that it was only after considerable hesitation that I decided to include descriptions of these insects in my "Handbook of the Gnats or Mosquitoes," and I believe that Mr. Theobald felt a similar hesitation when preparing his monograph.

Our ultimate decision to do so I personally regard as a mistake, which unnecessarily extended the scope of our books. These insects, in fact, are not gnats at all, their mouth-parts differing entirely from the piercing apparatus of those insects, and should really be considered midges with a wing venation that chances to resemble that of the *Culicidæ*.

Possibly this is a case of mimicry, though, as is often the case, it is difficult to see what advantage accrues to the midge from its resemblance to the gnats. His proposal, however, to promote the *Corethrinæ* into a distinct family, instead of transferring them to the *Chironanidæ*, may not, however, command such general approval, and still more his proposal to adopt the same course with regard to the *Anophelinæ*, for if, apart from the *Anophelinæ*, the *Culicidæ* are not a single family, and, it may be added, a remarkably natural one, it is difficult to understand what constitutes family resemblance.

It is perhaps only a natural evolution of the process which is rapidly reducing our conception of genus to the level of species, and each naturalist's decision must depend on his conception of the limits of these extremely elastic and ill-defined terms. It is obvious, however, that it only requires a sufficient extension of

the process to leave each species in a separate class of animated Nature by itself, and then I suppose we should have to start off again with the process of sorting it by instituting generoids, familoids, or some such nomenclature.

He has also been good enough to send me a reprint of his articles on the mosquitoes in Dr. C. Mense's "Handbuch der Tropenkrankheiten," which gives in comparatively short compass a thoroughly up-to-date epitome of the morphology of the family, methods of dissection, collection, preservation, general principles of classification, &c., as well as a short account of the life-history of the malarial parasite. It is well and liberally illustrated, though some of the photographs are not quite as convincing as might be desired, and certainly in some cases might advantageously be replaced by drawings.

"Centralblatt für Bakteriologie Parasitenkunde und Infectionskrankheiten," xxxix., p. 280.

SCHISTOSOMUM JAPONICUM.

Looss shows that *Schistosomum Cattoi*, Catto, 1905, is only a synonym for *S. Japonicum*, Katsurada (1904); the employment of the newer name (*S. Cattoi*) should therefore be dropped, and the older be always employed in speaking of this parasite.

"Journal of Infect. Dis.," 1905, p. 577.

It is well known that plague bacilli are occasionally met with enclosed in a capsule, and W. B. Wherry has met with the same peculiarity in a cocco-bacillus isolated from the liver of a plague rat. The oval capsule stained red with Romanowski; and cultivations answered to all the ordinary tests of *B. pestis*.

"Archives de Zoologic. Exper.," 1905, p. 101.

RESEARCHES ON THE HAPLOSPORIDIÆ.

Caullery, M., and Mesnil, F. The haplosporids are an order instituted by the authors in 1899. They are sporozoa allied to the microsporidia, but with quite different spores. These are always mononuclear, with large, easily demonstrated nuclei, and the cell plasma quite undifferentiated, and with no trace of polar capsule.

The authors have combined their own work with that of others on simlar types, and propose the following classifications.

They divide the order into three families:—

(1) *Haplosporidiidæ*. Spores with double envelopes, the inner denser and furnished with an opening, closed by a valve in *Haplosporidium*, or open in *Urosporidium*, in which it also has a long tail-like process and a lateral wing. Parasitic in annelids.

(2) *Bertramiidæ*. Spore envelopes without opening. Genus *Bertramia* and probably *Ichthyosporidium*, one of the species of which inhabits the stomachs, and the other causes large tumours in certain fishes, but is as yet insufficiently known to be definitely placed.

(3) *Cœlosporidiidæ*, in which the entire parasite encloses in a dense membrane, while the mononuclear spores developed within it remain nude. It includes, besides the type genus, *Polagcaryum*, Sternbell, and *Blastulidium*, Perez.

The authors enumerate many other genera which they believe come within the order, and believe that the *Haplosporidiæ* are nearest to the *Sarcosporidiæ*, but approach also the *Microsporids* and *Rhizopods*, and perhaps to the lower fungi, such as the *Chytridineæ*. The human parasite recently described in a nasal polypus by Minchin and Fantham, it will be noted, is a *Haplosporid*.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,	5/-;
100	,, ,,	6/-;
200	,, ,,	7/6;
50	Copies beyond four up to eight pages,	8/6;
100	,, ,, ,,	11/-;
200	,, ,, ,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

MAY 1, 1906.

IS MALARIA AS BLACK AS IT IS PAINTED?

THERE is an old tale, anent one of the old Georgian medical worthies—Abernethy, if memory serves us aright—that when posed by any difficult complication, he was accustomed to declare that "it was all gout." Nor, if we may judge from the writings of Haig and his school, is the doctrine by any means dead; for, indeed, the tendency of specialists generally to claim all disease as their own is proverbial.

For tropical countries malaria has, in this respect, always taken the place occupied by gout in temperate climates. Long before Laveran discovered the malaria parasite, the verdict of the tropical physician has generally been "it is all malaria," and the prominence that disease has recently attained as the pioneer of our knowledge of human protozoal disease has only added to its pre-eminence in this respect.

We have always been familiar with such terms as malarial rheumatism, malarial iritis, phlebitis, and what not, but it is tolerably certain that had these cases presented themselves to a European physician, suffering from what may be called the gouty bias, his diagnosis would have differed from that of his tropical colleague only in the substitution of the word "gouty" for "malarial."

Analysing the reports of such cases, we generally find that, beyond coincidence, the evidence in favour of the need of any qualifying word to that specifying the disease is remarkably scanty.

The maladies so described are usually of a sort that are rarely fatal, and even in cases that prove so, no evidence whatever is adduced to show that the malarial parasite is in any way responsible for the lesions recorded.

Take the case of "malarial" rheumatism: to the uninitiated they would appear mere ordinary cases of lumbago, sciatica, pleurodynia, and so on, such as are met with in all parts of the world.

The etiology, almost universally accepted elsewhere, is that they are due to the sudden chilling of the affected part, which brings about a congestion of the little sensory nerve bulbs that are scattered between the fibres of muscles, and especially amongst those of their tendinous insertions.

The reduction of temperature which thus irritates these very delicate structures is usually sharp, but of short duration, and leaves no visible impression on the surrounding structures, and as there has been no general chill, the patient, apart from his muscular pains, is little the worse, and shows no constitutional symptoms whatever. If resident in a hot country, he, doubtless, has suffered more or less from malaria, and may be debilitated from the strain of prolonged residence in a tropical climate, and these drawbacks may, no doubt, render him less capable of withstanding chills and other accidents, but this does not give us the right to regard his symptoms as a special and distinct variety of the disease from which he is suffering, still less to reduce the latter to the position of a mere symptom, indicative of malarial poisoning. Are we really to suppose that because a case of muscular rheumatism, occurring in a hot climate, may happen to have had one or more "touches of fever," his system is so "saturated with malaria" that the capillaries supplying the end bulb of the afferent nerves from his muscles are choked with parasites, or what are we to believe? Muscular rheumatism is very common in hot countries, because they have just the climates which most expose people to sudden chills. What need, then, is there of dragging malaria into the question?

Direct and obvious complications and sequelæ of really severe malarial infection belong to quite a different category, and are not the class of case we are considering. It is the subtle workings of "latent malaria" with which we are now concerned.

Another and more significant question, the importance of which is steadily forcing itself upon our attention is: How much of what we have been accustomed, clinically, to regard as malaria, is really of that nature?

For many years after Laveran made his great discovery our instruments and methods were so defective that but few succeeded in convincing themselves of its validity, and even after we had reached the stage of conviction, born of seeing undoubted parasites in fortunate preparations, our successes were usually so few, in proportion to our failures, that no one dreamed of regarding a negative result as in any way conclusive of the absence of malaria.

Fresh blood in a tropical climate is one of the most unstable of tissues, and with the utmost care to secure uniformity of method, two films from the same droplet of blood often present *post-mortem* changes of so different a description as to render any comparison obviously untenable. Under such circumstances what was to be read as an abnormality due to the presence of parasites, and what a fallacy due to *post-mortem* changes?

At this time malaria was, for us, like the first French Republic, "one and indivisible," and the puzzle was made all the worse by our meeting consecutively with different species of the parasite.

For these various reasons, the profession, even when convinced of the truth of Laveran's discovery, was, for purposes of diagnosis, generally driven back on the "clinical method." If one found parasites, well and good, the case was undoubtedly malarial; if not, it might, or might not be so, but few would reject the diagnosis on the strength of mere failure to find parasites.

With improvement in the methods of making and staining blood films, the physical diagnosis of malaria has become a comparatively easy matter, but there is still considerable reluctance to rely on the absence of parasites for a negative diagnosis, even after repeated examinations.

As recently as 1904, Powell, of Bombay, in the *Indian Medical Gazette*, 1904, p. 41, reporting on the examination of 3,413 cases of fever, found parasites present in 2,542 cases, and adds that, "of the remaining 761 cases, a definite diagnosis by clinical methods was made in 531, leaving 214 cases of fever whose cause is uncertain." Here, then, are at least this number of cases of indeterminate fever, which only a few years ago would undoubtedly have been ascribed to malaria; but what of the 531 cases diagnosed by "clinical methods," and what real ground is there for assuming them to be malaria at all?

Nothing more than that the general symptoms corresponded with one or other type of the very large group of feverish cases, which we were accustomed to diagnose as malarial in the days before we had any physical means of discrimination to rely on.

Added to this, it is now well established that, especially in children, malarial parasites may be present in the peripheral circulation, without producing any rise of temperature or other overt symptoms of ague; so that it does not absolutely follow that a fever is entirely, or even mainly, due to malaria because the parasites of that disease can be demonstrated in the blood. Everyone of any extended tropical experience well knows that malaria often shows itself as an awkward complication of any condition, whether morbid or traumatic, that throws a severe strain on the organism. This is notably the case in some epidemics of pneumonia on the very malarious Punjab frontier, where the coincidence of the two infections may be so general as to be almost the rule. That the added weight of the malarial recrudesence is far from improving the patient's chances goes without saying, but still, one does not regard the case as other than one of pneumonia, nor would it be fair to do so; and yet one might easily conceive the advancement of the thesis that the epidemic was one of "malarial" pneumonia, and not merely of pneumonia with more or less common malarial complication.

Another point that presents itself is the comparative rarity of serious cases of malaria in ordinary

tropical practice. Far more than nine-tenths of those met with are what are commonly spoken of as "touches of fever," lasting from a day to a week, or even more. Most of these are undoubtedly malarial, the parasites, usually of the "æstivo-autumnal" type, presenting themselves at the correct period, and disappearing coincidently with recovery. They are, moreover, mostly fairly amenable to quinine. Every now and again, however, a severe prolonged case of fever presents itself, in which quinine has no effect whatever. In the early stage, before the patient has been saturated with quinine, parasites may have been recognised in the blood, or they may not, and the case is diagnosed as malaria "by clinical methods"; but apart from customary habits of thought, what better ground is there for regarding the prolonged pyrexia as due to malaria, than in the case of pneumonia, with malarial complication.

So obvious is the fact that the vast majority of cases of malaria are of a very trifling character, that in the days before agglutination tests released us from so many perplexities, the diagnosis of malaria in the case of serious illness in a European was officially regarded in India with considerable suspicion, and it was considered as almost axiomatic that such cases must be referable to typhoid fever.

The mildness of the majority of attacks is equally proverbial in Africa, and the question naturally arises whether the serious fevers, occasionally epidemic in India, and the even more serious, but usually quite different, blackwater, and fulminating hyperpyrexia of Africa, have really any causation in common with the mild disease with which we are so familiar.

It is most significant that the severe fevers of India are usually quite different from the serious African fevers, for though hæmoglobinuria is occasionally met with in the former country, such cases, apart from this symptom, are far from otherwise presenting the clinical picture of blackwater fever.

It is notorious that malarial parasites are often conspicuous by their absence in that disease, and it must be repeated that their occasional association with the conditions above indicated definitely proves nothing more than complication; for if the discovery of parasites be equivalent to proof of malarial causation, then amputation of the leg and child-birth must often own a similar etiology.

Gradually, too, the origin of some of these indeterminate fevers is being elucidated. The final demonstration of the presence of Malta fever in India, noticed in a recent issue, accounts for a certain percentage of the serious cases that for want of a better diagnosis were mistaken for obstinately recurrent malaria. It is noteworthy that Bentley, of Assam, in the *Indian Medical Gazette*, 1902, p. 337, advanced the theory that kala-azar is really Malta fever, and his opinion was confirmed by Major D. Semple, of the Kassauli Pasteur Institute, by means of the agglutination test.

"Kala-azar" is always the malady that happens, for the time, to be in fashion, the native words really referring to any serious chronic malady, but it is clear that some of the cases, so-called, must be Malta fever, though the Leishman-Donovan parasite is now more in vogue, and doubtless does really account for a considerable number of the heterogeneous collection of cases brought on for treatment as kala-azar. Not so long ago the very investigators who are now most eager to make Leishman-Donovan parasitism and kala-azar synonymous were equally insistent of the theory that it was uniformly malarious in its etiology. A considerable percentage of cases, so-called by the natives, undoubtedly are chronic malaria, but more undoubtedly are referable to a variety of other chronic tropical maladies.

In view of the fact that malaria has already been deprived of kala-azar, will it be at all surprising should blackwater fever, and many of the other serious conditions now thought to be malarial, share the same fate?

Again, scarcely a month passes without our meeting with notices of protozoal parasites which are not malarial in the strict sense of the term. For example, W. Leonard Braddon, in the *Indian Medical Gazette*, 1903, pp. 168, 213, 291, describes a "mycoid body found in the red corpuscles in a form of remittent fever, prevalent in the Malay States" (*vide* also the JOURNAL OF TROPICAL MEDICINE, November 15th, 1901). Again, Jennings, in conjunction with Prof. A. Lingard, describes in the *Indian Medical Gazette*, May, 1904, a form of fever associated with a parasite they believed to be a piroplasma, and which was prevalent at a season when Anopheletes are practically absent.

Jennings' human hæmatozoa may or may not be piroplasma, as Lingard's conclusions in particular appear to be doubtfully received by the majority of protozoologists, but there is no practical doubt of the actuality of the parasites observed by Major Jennings, or of the validity of his general arguments as to their non-malarial nature, for these cases of cold weather and dry season fever, associated with the colourless, non-pigmented parasites, have long been a puzzle to many Indian observers, though they have, of course, been generally regarded as representing some phase of the malarial organism.

It would be easy to prolong this list, but the object of this article is not to produce a bibliography of the subject, but to suggest a judicial frame of mind in our consideration of the numerous cases, slight and serious, in which, though no parasites are evident, or in which, if present, do not correspond with any accepted stage of the known species of malarial hæmatozoa, but in which we have hitherto been too ready to take refuge in the time-honoured old diagnosis of "it is all malaria."

The question is by no means purely academical, as it is well known that many of this class of fevers are rather harmed than benefited by quinine, and it is very desirable that we should be able to save the patient a needless course of the drug, by reaching some means of arriving at an early and definite diagnosis.

THE *INDIAN MEDICAL GAZETTE* ON "GROWSING."

THE current (April) number of the *Indian Medical Gazette* pays us the compliment of printing *in extenso* our leading article on some of the causes of dissatisfaction in the Indian Medical Service, which appeared in our issue of February 1st.

That the editor of our contemporary agrees to differ from us is only what might be expected, as the *Gazette* is a good deal more than less an official publication, which no officer on the active list would dream of using as a means of ventilating his grievances, and hence is in a bad position to know what are the genuine sentiments of the rank and file of the service whose lot is cast up country, far away from Calcutta and the knot of men who, whether by luck or good management, occupy still desirable appointments in the second city of the Empire. The editor does not understand how the figure of thirteen men passed over for promotion on account of age was arrived at, and probably his information as to the age of officers qualified for promotion by their position on the list is more exact and up to date than ours, but for the purposes of our argument it matters nothing whether the accurate figures be 13 or 15 or 9. He admits that four men who were regarded as "in the running" were so passed over.

The gist of our complaint is that the Indian Government has hitherto given but scant encouragement to original research, and that the present rules as to superannuation bear hardly on men who have worked hard to specially qualify themselves for the service by taking house surgeoncies, honours examinations, and other post-graduate work.

With the above exception no attempt whatever is made to traverse the facts on which the complaints are based, though a lamely apologetic attempt is made to palliate them. Meanwhile, it remains an undoubted fact that no man who devotes really adequate time to his student career can reasonably expect promotion. As to the proposed remedies, opinions, of course, differ, as those who have been shrewd enough to enter young on a minimum qualification are naturally in favour of the existing state of things, but on the general indictment the writer of the *Gazette's* editorial is, so far, alone.

His contemptuous reference to officers who prefer to remain in military employ, whose fate, he says, is like to be "professional deterioration and finally, perhaps, supersession," appears to us to be, to say the least, in very doubtful taste, and will certainly not be relished by the very large section of the service so employed. He appears to forget that some one must perform the duties he so deeply despises, and that causes far other than laziness may determine an officer's preference for that branch of the service. As a matter of fact, however, a very fair share of promotion very properly falls to men on the military side, and though far from being enthusiastic admirers of the Indian Government's methods of dealing with its medical officers, we see no reasons for imputing to it the cynical injustice, implied in the editorial comment of our contemporary, of treating its military surgeons as an inferior and almost reprehensible body of men. He takes us to task also for failing to notice the hard case of the Sanitary Department, but all in good time. Pressure of space has prevented our returning to the subject during the last few issues, but we hope shortly to draw attention to a few other curled petals in the rose-bed of the Indian Medical Service.

ANÆMIA IN PORTO RICO.

A Commission, consisting of Drs. Jgaravidez, King, and Bashford, has been engaged in the investigation of Porto Rican anæmia since March, 1904. The Commission has issued a preliminary report of the work accomplished from June 1st to November, 1905. In all, 18,865 patients were treated by consecutive doses (usually 5) of thymol, or beta-naphthol, for the expulsion of the *Ankylostomum duodenale* (uncinaria), with the result that the large majority were cured. The Commission finds that 99 per cent. of cases of uncinariasis contracted the disease by way of the skin; ground itch on the feet and ankle being the indication that infection has taken place. The prophylaxis of the disease is to be secured by making the wearing of shoes compulsory; by insisting upon all infected persons using a latrine; and by, if possible, causing all workers on the soil to wash their hands and clean their nails before eating. It is satisfactory to know that the Commission is to be continued, and that the good work already done may be hoped to be amplified and extended.

MALTA FEVER IN SHANGHAI.

By Arthur Stanley, M.D., B.S.Lond., D.P.H.
Health Officer of Shanghai.

In view of the Editorial in the Journal of Tropical Medicine of December 15th, 1905, which tends to show that Malta fever is rare elsewhere than in Malta, the following laboratory notes may serve a useful purpose: During 1904 nine specimens of blood from suspected cases of Malta fever were examined, and seven of these gave the Widal reaction with the Malta fever organism. During 1905, of twenty-seven specimens from suspected cases of Malta fever, ten gave the Malta fever reaction. The Malta fever organism used in the laboratory was obtained originally from the Lister Institute, and the dilution of the blood used for the test was never less than 1 in 50. The blood was furnished from cases in Shanghai and from the Yangtse ports. Clinically the cases were reported as corresponding to Malta fever. It is proposed to examine the specimens of blood giving negative results with the typhoid bacillus for the Malta fever reaction, as the type of cases reported as typhoid fever in Shanghai are so mild (case fatality 10·2), and show such a tendency to relapse as to suggest the possibility of some of the cases returned as typhoid fever being Malta fever.

[In consequence of the great pressure on our space, we have been compelled to omit the Colonial Reports from the present issue.—Ed. *J.T.M.*]

RHINO-PHARYNGEAL LESIONS IN YAWS.

To the Editors of the Journal of Tropical Medicine.

Sirs,—The excellent paper in your Journal of February 15th, 1906, from the pen of Dr. James Farquharson Leys, deals with a disease which was brought to the notice of the profession in my treatise on yaws, published in 1891. I was then of the opinion that the rhino-pharyngeal

lesions, which I described, were later manifestations of yaws, and, though I could not trace the connection between this disease and the symptoms so described with scientific conclusiveness, I remember that there was at the time no doubt in my mind of the relationship which I assigned to them, any more than there would have been as regards syphilis and similar manifestations of the latter affection.

Dr. Nicholls, in his "Report on Yaws in the West Indies," 1894, attributed these symptoms to tuberculosis, which, he said, was very prevalent in the district in which they occurred, but this is the only reason which he gives for considering them to be of tuberculous origin. As yaws, however, is far more prevalent there than tuberculosis, it would seem to me that the argument, based on coincident prevalence, would be far more in favour of a frambœsial than of a tuberculous origin. I am not aware that those who attribute these symptoms to syphilis adduce any better reason than the above in support of their theory. As Dr. Leys has pointed out, these lesions are met with in places in which syphilis is rarely seen or has never existed. Dr. Daniels encountered them in Fiji, where there is no syphilis, and he certainly had no reason to assign them to tuberculosis.

I wish to explain at this point that the destructive ulceration of the nose and palate which I attributed to yaws did not attack bone. In this fact there appears to be a difference between Dr. Leys' cases and mine. When I met with the only case in the district in which the bones of the nose and palate had been destroyed, I wrote to Mr. Hutchinson on the subject, requesting his opinion, and he assured me that his experience had led him to the conclusion that lupus could safely be excluded in such instances, as it never attacked bone, and that he considered the case to be one of syphilis. Dr. Nicholls refers to the same case in his report already alluded to as an example of syphilis in a yaws patient.

It would seem from Dr. Daniels' description of the naso-palatine symptoms which he observed in Fiji that the lesions in his cases were limited, as in mine, to a destructive ulceration of the soft tissues and that, in this respect, they also differ from the conditions mentioned by Dr. Leys, who states that "the disease begins in the soft parts, but after reaching the soft palate, and eating its way through its entire thickness, attacks the bone of the palate and nasal septum, finally destroying these entirely."

While in Dr. Leys' cases the destruction of tissue was so extensive as to attract the attention of a casual visitor, the noseless condition of the patient revealing his disease, in mine there was practically no outward manifestation of the affection.

I would not, however, conclude that the lesions in the patients in Guam had a different origin from those observed by me in Dominica, or by Dr. Daniels in Fiji. It is possible that the same cause, owing to peculiar conditions, had produced a severer form of the same disease in the first-mentioned place, whether the symptoms be those of a special local disease or a later manifestation or sequela of yaws. It would be strange if, supposing the symptoms to be those of a disease, *sui generis*, or rather of two different local special diseases, the lesions in one affection should be limited to the soft parts, and in the other should include both them and the bony structures.

Is there anything in European pathology which can guide us towards an opinion as to the nature of these symptoms? Certainly, considering the ages at which they appear and the absence of any evidence of hereditary syphilis, it is not at all probable that syphilis can account for them in the majority of the cases in which they are observed. Of the thirty cases seen by Dr. Leys during 1904, as many as seventeen were school children. On the other hand, similar lesions are sometimes the result of scrofulous influence. Cases have been reported in which an obstinate ulceration of the pharynx in scrofulous children has extended to the tissues of the soft and hard palate as well as to the nares, until the nose falls in and the greater portion of the soft and hard palate are destroyed. Can the lesions under consideration have had a similar origin? The general condition of the patients so afflicted does not certainly suggest a scrofulous taint. "The patients," says Dr. Leys, "remain muscular, well fleshed, and well blooded," nor were there any signs of scrofula in those who came under my observation.

Dr. Leys very naturally points to the fact that these lesions have only been found in certain places and not in others in which yaws prevails as extensively, as a proof that they are not connected with yaws. He instances Nevis as a place in which yaws has been particularly prevalent for a number of years and in which such symptoms have never been observed. It is certainly the case that at the time I met Dr. Leys, I did not remember having met any case in Nevis in which there was any ulceration of the nose or palate. I have since then, however, found notes of three cases which have been under my care—patients aged 15, 17, and 19 respectively—in which the septum of the nose has been ulcerated, and a hole left in it the size of a sixpence. The mucuous membrane is studded with small encrusted tubercles. This condition, it will be urged, does not in any way resemble the severe destructive ulceration of the nose and palate which is under consideration. This is true; but may it not be a milder form of the same process? (I was informed by the mother of one of the patients, a muscular, well-developed young fellow, aged 19, that he had never had yaws.) Is it not possible that the severity of such lesions may be proportionate to the severity of the other symptoms of yaws? Yaws, as I have seen it in Nevis, is very different from that disease as it came under my notice in Dominica. Here, in Nevis, the cases are all in children under 12 years of age, and the cutaneous lesions (except the initial ulcers) consist only of "squames" generally, and occasionally of papules. Nowhere have I seen any of the granulomata with crusts which are so commonly observed in Dominica—both in children and adults. This difference may be due to the fact that the children affected with yaws in Nevis have received more regular medical care than those in Dominica, and that they have been treated with small doses of mercury, which have modified the symptoms of the disease; or it may be that the affection in Dominica, owing to climatic conditions (greater dampness, &c.), is of a more virulent type. Allowing, therefore, that the destructive ulceration of the nose and palate is due to yaws, we should expect to find this condition most pronounced in places in which the other symptoms of the disease are most virulent, and *vice versa*.

Another point to be remembered in this connection is the possibility, to which I have already drawn attention in a previous paper, viz., that yaws may manifest itself both as a local as well as a constitutional disease. While the "squames" and papules of yaws may be cutaneous manifestations of the constitutional affection, the encrusted granulomata and the later symptoms may be the result of the local action of the yaws microbes. Similarly the destructive ulceration of the nose and palate may be caused by these microbes acting directly on the tissues in places in which the disease exists in its most virulent form.

Your obedient servant,

J. Numa Rat

PRELIMINARY STATEMENT ON THE RESULTS OF A VOYAGE OF INVESTIGATION TO EAST AFRICA.

By R. Koch.

(*Translated from the German by P. Falcke.*)

(*Continued from page* 105.)

The conditions thus resemble those of the malaria parasite, which at the commencement of their sexual stage also exhibit a similar differentiation; they, too, having some forms poor in plasma, with plentiful close chromatin, and others rich in plasma but with loose chromatin. I conclude, therefore, that here, too, we have an instance of sexual differentiation, the forms rich in plasma representing the females, and the slender ones, poor in plasma, the males.[1]

Whether or not these forms copulate, or whether, as in the malaria parasite, microgametes are first formed, I cannot say, but so far as my observations go the latter process appears the more probable.

In the hindmost part of the stomach, moreover, forms are found which appear to me to represent the further development of the fertilised females. These are very large trypanosomes which possess only one blepharoplast with its flagellum, but several nuclei. The number of nuclei is sometimes two, mostly four (figs. 18 and 19), and in a few cases even eight.

Nuclear fission is, indeed, known to occur even in the simple (asexual) multiplication of trypanosomes, but in such cases the number of blepharoplasts, with their flagella, always equals that of the nuclei.

It stands to reason, therefore, that we have to do with something else than simple fission, as here the blepharoplasts do not multiply, but only the nuclei. Although I have not witnessed the process, I consider it likely that these multi-nucleated trypanosomes split up into a corresponding number of parts, and so form the extremely minute forms which I have so frequently met with in infected flies.[2]

These latter are simple globular cells, with a single nucleus (fig. 20), and exhibit all transitions to those with nucleus and blepharoplast, to which a flagellum is afterwards superadded (figs. 21 and 22). The shape then becomes elongated, and more and more like the trypanosome. Usually these young forms may be recognised by the blepharoplast being placed anteriorly to the nucleus, towards the flagellar end of the organism (fig. 23). It is only later that it moves near to the nucleus and gradually makes its way to the posterior end of the trypanosome.

Besides these, other forms appear for which I can as yet furnish no satisfactory explanation. One of these consists of longitudinal bundles of long, thin trypanosomes which are often rolled up, and look as if they were produced by the segmentation of a large cell. There are also tape-like trypanosomes, often of remarkable length, with obtuse extremities. In these forms the blepharoplast is placed anteriorly and the flagellum is very short (fig. 24).

It may be remarked that in the fluid squeezed from the proboscis of the fly there are, besides other forms, nearly always some trypansomes which resemble the trypanosomes of the blood of infected animals in size and appearance. It may be assumed that infection is transmitted by these. I failed to infect rats by means of the trypanosomes from the stomach of flies.[3]

As yet, too, I have failed to get any positive results by making Glossina feed on animals infected with trypanosomes. When the flies were fed on oxen which had just been attacked with tsetse disease, and harboured many trypanosomes, most of the parasites disappeared as the blood was digested. The trypanosomes refused to develop, and no permanent infection of the flies was found to result. It was only when the flies were made to bite beasts (oxen, mules) which had been long infected, and only incidentally harboured a few trypanosomes in their blood, that a few flies became infected. I am therefore inclined to suspect that all blood trypanosomes are not capable of infecting Glossina, but only such as happen to be at some stage with which we are as yet insufficiently acquainted. It seems probable that the infective type of trypanosome is to be found in those large game animals which are little susceptible to tsetse, such as antelopes and buffaloes.

I have frequently found infected flies in regions where they could have been infected by no other agency than that of large game, in the blood of which, as is well known, only very few trypanosomes are present. In the Lungera Valley, where the highest percentage of infected flies was found (17·4 per cent.), there were no oxen, and only very few antelopes. On the other hand, there were goats and sheep which were apparently quite healthy, but most of them had a few trypanosomes in their blood.

In regard to the Glossina themselves, it should be noted that the males as well as the females suck blood, and that both sexes become infected and are capable of conveying infection.

G. fusca flies and bites by night. In order to keep this species alive for any length of time they should be given the opportunity of sucking blood every two or three days. The males of *G. fusca* usually sit on shrubs and bushes or on the ground by the wayside. The females are shier than the males, and only appear when they scent animals. Hence flies caught away from animals are mostly males. Amongst the flies caught on animals (mules, asses, oxen) there are always some females, and occasionally they may be as numerous as the males.

The females do not lay eggs like most other diptera, but a single whitish larva, which in a few hours changes into a pupa. *G. fusca* gives birth to only a single larva at a time, at intervals ranging from ten

[1] In my detailed work I shall mention in how far these sexual forms have been seen by other observers.

[2] Rabinowitsch has already seen the same young forms in the trypanosoma of rats, moreover Novy and M'Neal have observed them in their cultures of trypanosomes; possibly also Castellani saw them in the cerebro-spinal fluid of sleeping sickness patients.

[3] The Sleeping Sickness Commission likewise had negative results in their experiments to transmit the trypanosoma from *G. palpalis* to monkeys. "Reports of the Sleeping Sickness Commission of the Royal Society," No. vi., p. 286.

to twenty days, according to the temperature of the the air, so that the females produce but two or three progeny in a month. The propagation of the Glossina, therefore, is very slow compared to that of most insects. This appears to be the weakest point in the cycle of infection of the trypanosomes, and may, perhaps, offer a standpoint for an effective method of combating trypanosome diseases.—(*Deutsche Medizinische Wochenschrift, November* 23*rd*, 1905.)

JOURNAL OF THE R.A.M.C., APRIL, 1906.

REPORTS OF THE COMMISSION APPOINTED BY THE ADMIRALTY, THE WAR OFFICE, AND THE CIVIL GOVERNMENT OF MALTA, FOR THE INVESTIGATION OF MEDITERRANEAN FEVER, UNDER THE SUPERVISION OF AN ADVISORY COMMITTEE OF THE ROYAL SOCIETY.

(*Reprinted by permission of the Royal Society and Colonial Office.*)

I.—GOATS AS A MEANS OF PROPAGATION OF MEDITERRANEAN FEVER. By Major W. H. Horrocks and Captain J. Crawford Kennedy.

ABSTRACT.

In Part III. of the Reports of the Commission a preliminary note was published on this subject, in which it was shown that goats in Malta suffer from Mediterranean fever, and excrete the *Micrococcus melitensis* in their milk and urine. The further study of this subject may be divided into the following parts:—

(1) Examination of goats living in pens (*a*) in the immediate neighbourhood of Valletta and Sliema, and (*b*) in the more remote parts of the Island.

(2) Experiments made to determine the possibility of infecting animals by feeding them on milk cultures and infected milk

(3) Experiments to determine the mode in which the goats themselves become infected.

(4) Experiments to determine whether it is possible to destroy the *M. melitensis* by Pasteurisation of the infected milk.

General Summary of Results.

(1) Judged by the serum reaction, 41 per cent of the goats in Malta are infected.

(2) Ten per cent. of the goats supplying milk to various parts of Malta appear to excrete the *M. melitensis* in the milk.

(3) The excretion of the specific microbe may continue steadily for three months without any change occurring in the physical character or chemical composition of the milk, and without the animal exhibiting any signs of ill-health.

(4) Some infected goats may lose flesh and their coats may become thin; they may also suffer from a short hacking cough. A febrile condition, however, has not been observed.

(5) Goats may have a marked blood reaction (1—100), and yet never excrete the *M. melitensis* in the milk.

(6) If the blood serum or milk does not agglutinate the *M. melitensis*, the specific microbe is not found in the milk.

(7) There is no constant relation between the amount of agglutinins in the milk or blood and the excretion of *M. melitensis* in the milk; but the higher the dilution of the serum which agglutinates the *M. melitensis*, the greater is the probability of finding the *M. melitensis* in the milk.

(8) The excretion of the *M. melitensis* in the milk may be intermittent, appearing for a few days and then disappearing for a week or more.

(9) A blood reaction may exist for some weeks before the *M. melitensis* is excreted in the milk.

(10) If blood cannot be obtained, the milk reaction with the *M. melitensis* (Zammit's test) is a good indication of infection.

(11) The milk agglutination test is a surer indication of the *M. melitensis* being excreted in the milk than the serum reaction.

(12) Monkeys and goats can be infected by feeding with cultures of *M. melitensis* isolated from milk, and also by feeding with infected milk itself.

(13) The incubation period in feeding experiments appears to vary between three and four weeks.

(14) Monkeys infected by feeding sometimes suffer from a typical wave of fever and lose flesh, at other times they show no obvious signs of ill-health, and may even gain in weight.

(15) When monkeys become infected by feeding with milk the lymphatic glands always contain far more colonies of the *M. melitensis* than the spleen. This fact suggests that the specific micrococci contained in the food are carried to the lymphatic glands and there undergo considerable multiplication. It has not yet been proved that the mesenteric glands are always infected at an earlier date than the femoral and axillary glands, but Experiment IV., feeding with milk, shows that this may be the case at times.

(16) It has been demonstrated that goats may become infected by feeding on dust polluted with urine from cases of Mediterranean fever. The excretion of *M. melitensis* in the milk resulting from such infection is a late phenomenon, only appearing about seventy-four days after the blood reaction has developed.

(17) It has not been possible yet to convey infection from goat to goat by means of mosquitoes or *Stomoxys calcitrans*. If mosquitoes do carry the infection, it seems more probable that the microbe is transferred from man to goat, than from goat to goat.

(18) Agglutinins may be transferred from the mother to the fœtus *in utero*. Pregnancy appears to follow a normal course in infected goats.

(19) Pasteurisation (68° C. for ten minutes) destroys the *M. melitensis* present in infected goats' milk.

II.—THE INCIDENCE OF MALTA FEVER AMONGST THOSE EMPLOYED IN THE MILITARY HOSPITAL, VALLETTA, DURING THE YEAR 1905. By Captain J. Crawford Kennedy, R.A.M.C.

Kennedy finds some evidence of the transmission of Malta fever by mosquitoes; of the liability of persons engaged in nursing, night duty, and cleaning latrines to contract Malta fever; and of the greater

prevalence of the disease in the Valletta Hospital staff compared with other hospitals in Malta.

III.—The Pathogenic Mosquitoes of Jamaica.
By Major F. M. Mangin, R.A.M.C.

In Jamaica, one has unequalled opportunities of making the acquaintance of certain species of this group of the diptera, each of which in itself is the carrier either of malaria, filariasis, or yellow fever, respectively. The species alluded to are: *Culex fatigans*, the carrier of filariasis; *Stegomyia fasciata* and *S. mosquito* (Robineau-Desvoidy), the carriers of yellow fever; and the five species of Anopheles found in this island; these are—*Anopheles punctipennis*, *Arribalzagia maculipes*, *Cellia argyrotarsis*, and *Cyclolepidopteron grabhamii*, together with *Cellia albipes*, the commonest form of Anopheles. In addition, there are numerous other species of Culex, but these are not yet proved to be pathogenic.

Miscellaneous.

SANTYL—A NON-IRRITATIVE INTERNAL ANTI-GONORRHŒIC.

By Dr. H. Bottstein.
Hamburg.

(*Translated from the German by P. Falcke.*)

Dr. Vieth, of Ludwigshafen-on-the-Rhine, reported on "The Mode of Action of the Balsams" in the *Medizinische Klinik*, No. 5, 1905, and made a statement regarding the preparation and effect of a new balsam, *i.e.*, santyl. According to these statements this drug is preferable to other balsams on account of its non-irritative qualities and its tastelessness. Up to the present R. Kauffmann reports on forty-five cases treated with santyl (*Monatshefte f. prakt. Dermatologie*). He states that santyl is a remedy possessing the advantages of a new santal preparation, while also exhibiting the specific effects of salicylic acid; it is, in addition, free from the unpleasant after-effects of other balsams. Santyl is, moreover, odourless and tasteless, and can be taken as oil in the form of drops. It has yielded good results in the case of female patients with gonorrhœa. Sensitive women who could not swallow the capsules, and objected to other preparations on account of the taste or smell, took santyl in drops without aversion. In santyl, also, the irritative effects on the kidneys are less than in the former preparations. In my total of sixty patients treated with santyl only two complained of slight transient sensitiveness in the region of the kidneys. One patient refused to take the oil, asserting that he had an idiosyncrasy against all kinds of oils. Recently, also, santyl can be obtained in capsules, but it is seldom used in this form except in exceptional cases; travellers, for instance, prefer them in this form on account of their convenience. The progress that santyl represents must not be under-estimated. In those cases, also, in which, for obvious reasons, secrecy has to be maintained, it does not betray the patient by any evil odour, as is known to be the case in the other sandal preparation.

I would like to call attention to the fact that I have only taken fresh infections under consideration, as, in chronic gonorrhœa, the effects, as a matter of course, are not so striking. For acute gonorrhœa, with its subjective disorders, santyl is an actual specific, and is particularly valuable when the course of the infection is severe and there are marked symptoms of inflammation. Kauffmann observed favourable results in posterior gonorrhœa, and my experience confirms his opinion. Eighteen cases of gonorrhœa of the posterior urethra, which I treated with santyl, ran a light course without complications. The urine also rapidly became clear, and only in one case did I find it necessary to exhibit santyl combined with urotropin, as has been recommended by others.

Statements are frequently made that one drug or the other is able to cure acute gonorrhœa without local treatment. Other authorities, on the contrary, assert that gonorrhœa cannot be cured by means of internal remedies only. P. Meiszner is most positive, and writes as follows in his "Experiences with Arhovin": "It must be understood from the start that a treatment for gonorrhœa which is wholly internal is impossible. Internal preparations for gonorrhœa must therefore only be regarded as adjuvants." Kauffmann is no less energetic in his assertions that it is impossible to cure gonorrhœa without local treatment, and all objective observers will agree with him. If this standpoint is taken, and it is justified by practical experience, the effect of balsams will still be valued, but to a limited extent. The subjective disorders which very frequently trouble patients can mostly be removed by the balsams.

The effect of the various balsam preparations which are used in the treatment of gonorrhœa is about the same, whether balsam, copaibæ, or ol. santali is used. Gonosan, which has recently been highly recommended, is said by some authorities to possess anæsthetic properties; nevertheless, other sandal preparations which do not contain kawa (such as santyl) also remove the pains. There is one great difference between the various balsam preparations, namely, the accessory effects. Copaiba balsam frequently causes exanthema, and has therefore been abandoned in favour of sandal oil, in which cutaneous symptoms occur much less frequently. Sandal oil, however, also has several disadvantages, as is well known. Apart from the rough taste which is covered by taking this preparation in capsules, disorders of the stomach or renal pains occur in quite one-third of the cases. The same applies to gonosan. I cannot say that I have observed that it has less unpleasant after-effects than pure East Indian sandal oil; it is also not pleasant to take, as it contains 80 per cent. of pure sandal oil.

In santyl the principal ingredient of sandal oil, santalol, is chemically combined with salicylic acid, producing a neutral and almost tastless oil. Santyl is chemically analogous to salol, which is the salicylic acid combination of phenol. Such combinations pass through the stomach almost unchanged and are only split up and absorbed in the intestine. The disagreeable effects on the stomach are thereby correspondingly decreased. Santyl can be demonstrated in the urine as early as one hour after it has been taken.

I have used santyl altogether in sixty cases of acute gonorrhœa. It is not necessary to give the histories of the disease, but I may remark that amongst my cases

there were several particularly severe ones in which santyl gave the most satisfactory results. In two cases also with terminal hæmaturia convalescence set in soon, the hæmorrhage ceasing in two and three days respectively, while the pain during micturition, which at first was very great, quite disappeared.—*Medizinische Klinik*, No. 11, 1905.

SANTYL-KNOLL.

A new sandal-wood preparation for the internal treatment of gonorrhœa has been introduced by Knoll and Co., 27A, St. Mary-at-Hill, London. The preparation may be taken in drops or capsules; it is free from disagreeable smell and taste, and does not cause gastro-intestinal irritation nor offensive eructations.

Reviews.

BERI-BERI.—"OBSERVATIONS IN THE FEDERATED MALAY STATES ON BERI-BERI." By C. W. Daniels, M.B.Camb., M.R.C.S., late Director, Institute for Medical Research, Kwala Lumpur, F.M.S. E. G. Berryman and Sons, Blackheath Road, London, S.E. 1906. Pp. 105. Price 3s. 6d.

Published as Part I. of vol. iv. of "Studies from Institute for Medical Research, Federated Malay States," Dr. Daniels work on beri-beri is deserving of close attention. The recent works on beri-beri by Dr. Hamilton K. Wright, Dr. Travers, Dr. Braddon, Dr. Haviland, Dr. Durham, Dr. T. S. Kerr, and many other observers, are reviewed and considered in all their bearings, and their several theories and conclusions judicially handled. Every sentence in Dr. Daniels' observations is written with evident care, having due regard for the work and opinions of others, and a keen appreciation of their efforts to elucidate the cause of beri-beri. It is impossible to quote from a book in which every paragraph bears directly on the context, for the argument is so closely and precisely followed that extracts would be meaningless. We can only state the general conclusions arrived at by Dr. Daniels. These are:—

(1) "That beri-beri is an infectious disease. As a rule, a short period of incubation and a period of exposure of less than three months is requisite for full development of the disease where the 'endemic index' is high.

(2) "That there is no definite proof that an intermediate host is required, but the balance of evidence is against its being conveyed by earth, air, water, or food, or contamination with sewage or other fæcal matter.

(3) "That there is some evidence that for a short period only after the occupation of small spaces, beds, bedrooms, &c., the 'poison' or carrier of infection may remain.

(4) "That food, either as regards quantity and quality, its nature or relative proportions, may have an effect on the susceptibility of the patients, though the proofs are not conclusive, but is not the causative agent.

(5) "That if an intermediate host for the unknown parasite is required, it must be either a cimex or a pediculus. That pediculi as carriers would better explain the incidence of the disease than any other blood-sucker.

(6) "That a closer enquiry into the earlier stages of the disease is required. That where opportunities for such an enquiry occur, renewed attention should be bestowed on the blood and tissues, with a view to determining the presence or absence of any protozoon.

(7) "Prophylaxis. That in view of the failures of various attempts at disinfection of buildings and places, and of various modifications of diet to have marked effects, more attention should be paid to limiting the chances of personal infection, and that particular attention should be paid to the personal cleanliness, freedom from vermin, and isolation of early or trivial cases of the disease.

"The importance of the disease, affecting as it does the imported labour of the country, causing prolonged sickness and frequently death, cannot be over-estimated in a rich country so sparsely populated as the Federated Malay States. There is evidence that the disease is less common and less fatal than a few years ago; but directly, and as a complication of other diseases, it is still the main cause of the high mortality in the healthiest period of life, amongst the Chinese.

"Every earnest endeavour to improve the conditions of life that has been made in the past has resulted in an improvement. The number of cases is diminishing, and the mortality from the uncomplicated disease less than ever.

"The scope of the enquiries has, as a result of the observations of numerous workers, been diminished, and the prospects of an early solution of the cause of the disease and of its mode of propagation may be confidently anticipated by future workers at no distant date."

We congratulate Dr. Daniels upon a book which is a model of scientific literary effort, and one which places our knowledge of beri-beri of to-day accurately before us.

New Instruments, &c.

ILLUSTRATED PRICE LIST OF ELECTRO-MEDICAL APPARATUS.—K. Schall, 75, New Cavendish Street, London, has sent us an excellently illustrated catalogue of electro-medical apparatus. The address will, no doubt, be useful to readers.

BECK, R. and T., Ltd., 68, Cornhill, London, have introduced a new form of "Ehrlich" Eyepiece for counting blood corpuscles which fits their "London" Microscope.

Drugs and Remedies.

HETRALINE: A URINARY DISINFECTANT. — Dr. del Amo, in a paper on the antiseptic value of hetraline, states that, in doses of seven grains, repeated four times daily, this drug was useful in cases of bacteriuria. In acute and chronic cystitis, catarrhal urethritis, and the urethritis due to stricture, hetraline is as effective as urotropin, and has the advantage of being less irritating to the tissues.

Medical Notes.

THE EDIBILITY OF THE SPLEEN.

The reason why the spleen, of all abdominal solid organs, is practically the only one not used for human food, is difficult to explain. Dr. Williams, in *American Medicine*, February 10th, brings forward a plea for its consumption, and states that when stewed the spleen is pleasant to taste; it must be cooked and eaten when quite fresh. Considering the physiological importance of the spleen, it is peculiar it has never been used either as a medicinal agent nor as a part of ordinary diet.

CHOLERA.

In the Philippines cholera is spreading, especially in the villages along the coasts and on the rivers. As the villages drain directly into the rivers, a continuance of the epidemic is probable.

SMALL-POX IN CALCUTTA.

Between December, 1905, and March 1st, 1906, it is estimated there have been 5,000 cases of small-pox in Calcutta.

CREEPING DISEASE.

Moorhead, J.D., in the *Texas Medical News* of February, describes a skin affection in a boy, aged 5, said to be suffering from Brazilian worm in his foot, which has been given the name "creeping disease." The infection was believed to come from a family from Brazil. The worm travels in the layers of the epidermis at the rate of from ½ to 1 inch in twenty-four hours, leaving a raised line of epidermis about ½ inch wide. The treatment consisted of excision of the part at the point where the worm is advancing, or by freezing this neighbourhood with ethyl chloride spray.

SEVERAL readers of the Journal have asked for information concerning the meaning of the opsonic index. Stated shortly, it may be explained as follows: Wright and Douglas have shown that washed leucocytes possess no phagocytic power when brought in contact with staphylococci, but if normal serum or blood plasma is first added to the staphylococci and then brought in contact with washed leucocytes, the phagocytic action of the leucocytes is re-established. This power seems resident in a substance contained in the serum termed opsonin; to ascertain the opsonic power of a given specimen of blood. the volume of serum is added to equal volumes of a bacterial suspension and of washed leucocytes. After this mixture has been incubated at 37° C. for fifteen or twenty minutes, microscopic specimens are mounted, fixed and stained, and the bacteria within the leucocytes counted. The number of bacteria within the leucocytes divided by the number of leucocytes counted gives the opsonic index.

Notes and News.

THE growing of cotton in the Federated Malay States is attracting some interest. The cotton, although of qualities somewhat inferior to Egyptian cotton, is stated to be of fair quality, and it is hoped the cultivation may prove remunerative.

MALARIA AND MOSQUITOES.—In Barbados the absence of Anopheles mosquitoes and of malaria is a fact which is well known. The explanation of this phenomenon has been lately attempted to be explained by Mr. C. K. Gibbons to the presence of a small fish, known locally as "millions" (*Girardines versicolor*), which preys on the larvæ of mosquitoes.

Yet another medical journal was added to the long list of American medical journals on January 1st, 1906, when No. 1 of vol. i. of the *Bulletin of the University of Nebraska* appeared. Henry B. Ward contributes an elaborate paper on "*Filario loa.*"

YELLOW FEVER.—Gorgas states that he has known the Stegomyia mosquito live 150 days in captivity.

RESULT OF THE EXAMINATION FOR THE DIPLOMA OF TROPICAL MEDICINE, UNIVERSITY OF LIVERPOOL, HELD ON MARCH 26, 27, AND 28, 1906.

Examiners.

External Examiner, Colonel D. Bruce, C.B., F.R.S.; Internal Examiners, Professor R. Ross, C.B., F.R.S., D.Sc., F.R.U.C.; J. W. W. Stephens, M.D.; C. J. Macalister, M.D., C.M.; R. Newstead, A.L.S, F.E.S., Examiner in Medical Entomology.

The following candidates have been recommended for the Diploma in Tropical Medicine:—

F. A. Arnold, M.B., D.P.H.
J. B. Bate, L.S.A.
J. Dundas, M.B.
N. Faichnie, Major R.A.M.C., M.B.
D. F. Mackenzie, M.B.
A. Pearse, Major R.A.M.C., D.P.H.
R. D. Willcocks, Captain I.M.S., M.B.

RESULT OF THE EXAMINATION, LONDON SCHOOL OF TROPICAL MEDICINE, 20TH SESSION, APRIL, 1906.

The following candidates passed the examination for the Certificate in Tropical Medicine.

Captain S. Anderson, I.M.S., M.B., C.M.Glas., 1896, with distinction.

H. E. Arbuckle, M.B., Ch.B.Edin., 1900, with distinction.

Captain B. H. Dutcher (U.S. Army, M.D.Coll. P. and S. Columbia University, New York), with distinction.

G. J. Pirie, M.B., Ch.B.Aber., D.P.H. 1905 (Colonial Service), with distinction.

A. G. Eldred, M.R.C.S., L.R.C.P. (Colonial Service).

H. Kramer, M.B., Ch.B.Edin., 1902.
P. H. MacDonald, M.B., Ch.B.Edin., 1899 (Colonial Service).
B. Moiser, M.R.C.S., L.R.C.P., M.B.Lond., 1904 (Colonial Service).
A. Reid, M.R.C.S., L.R.C.P., 1900, D.P.H.Durh., 1902, M.B.Durh., 1903.
W. Rogers, M.B., B.Ch.Edin., 1900 (Colonial Service).
W. E. Ruttledge, M.R.C.S., L.R.C.P., 1900.
A. L. Wykham, M.D.Howard Univ., 1887, L.S.A., L.M.

The "Ultra Microscope."

The ultra microscope, designed by Liedentopf and Szrgmondy, and constructed by Zeiss, has had no better success in detecting the organism of yellow fever than the familiar oil immersion. The idea of this instrument is not, strictly speaking, to bring into view, but to notify, the presence of bodies too minute for recognition by ordinary microscopic vision. Such bodies appear as shining points without any definite outline. But even in normal serum the points are so numerous that it is impossible to draw any conclusion as to the presence or absence of specific organisms.

The instrument has been tested in yellow fever by M. Otto and R. O. Neumann, who have recently made an expedition to Brazil to study that disease, but with no better result than their predecessors, except perhaps that they have bearded the lion of disease without loss of life or health, which alone should be a matter of congratulation in the case of a malady to which so many investigators have fallen victims.

Protection by Serum and Toxin.

A good deal of work is being done in various laboratories with the view of producing an anti-trypanosomiasis serum and to those interested in the subject the following references of recent works may be useful. In the current issue of the *Bull. de l'Institut Pasteur* abstracts are given of the following papers on this subject: Dresing, in the *Archiv. f. Schiffs. u Trop. Hyg.*, October, 1905, p. 427; Schilling, *Zeitschr. f. Hyg.*, 1905, p. 149; and Kleine and Mollers, *Zeits. f. Hyg.*, 1906, p. 229. The results are encouraging, distinct immunity being evidenced in experimental work, but their attempts to protect transport animals do not appear to have been so satisfactory, and the injections themselves do not appear to be entirely without danger.

In the same issue abstracts are given of two papers on the production of immunity against cholera infection by S. Seikouski and by K. Schmitz in the *Persglad lekaroki*, 1905, p. 746, *et seq.*, and the *Zeitschr. f. Hyg.*, December, 1905, p. 1, respectively, but neither appear to have succeeded in conferring immunity of sufficient duration to be of practical use in dealing with cholera.

In countries where cholera is endemic, or, at least, where the danger recurs every year, nothing short of an immunity as long as that conferred by vaccination against small-pox is likely to be extensively adopted, as it is too much to expect people to undergo the by no means considerable inconvenience and even risk of a protective inoculation every few months or so, and, in a minor degree, the same remark applies to the case of plague.

It must be remembered that for a certain length of time susceptibility is increased by the whole class of protectives which rely on the introduction of toxins, and that even the injection of the serum of immune animals is not without its dangers, so that for practical purposes what is required in either toxin or anti-toxin is that its effects should last long enough to be available for use at times when the plague *pro tem* is not epidemic.

French and English Mortality and Sickness on the Gold Coast.

The *Lancet* of February 3rd contains an instructive abstract of the health statistics of the French tropical colonies based on a report in the *Archives de Medecine et de Pharmacie Militaires* for January, 1906, from which we extract the subjoined table:—

French colonial troops stationed at—	Europeans				Natives		
	Average Strength	Sickness per 1,000	Deaths per 1,000	Invalids per 1,000	Average Strength	Sickness per 1,000	Deaths per 1,000
1903							
Western Africa	1,862	1,181	21·4	179·9	5,138	282	12·8
Annam-Tonkin	10,248	886	24·3	118·3	13,777	606	21·9
China Reserve Brigade	2,771	848	11·5	101·4	1,087	478	9·4
China Army of Occupation	1,672	924	10·1	61·0	—	—	—
Cochin China ..	2,121	1,285	33·0	205·5	1,625	1,063	47·3
Madagascar ..	4,812	1,091	17·6	187·2	7,202	376	12·9
Réunion	862	878	10·4	92·8	—	—	—
Martinique ..	914	1,611	10·9	214·4	—	—	—
New Caledonia	728	365	12·3	79·6	—	—	—
Tahiti	103	335	0	19·4	—	—	—
St. Pierre and Miquelon	14	143	0	0	—	—	—
India	4	0	0	0	142	795	7·0
Tchad	72	986	27·7	13·8	750	811	22·3
Guadeloupe ..	173	2,132	11·5	404·5	—	—	—
Guiana	194	644	5·1	242·2	—	—	—
	26,550	993	19·8	139·7	30,621	523	18·7

It is interesting to compare French results with British in West Africa.

The French troops so employed are, it must be remembered, a long service corps, composed of men who have already gone through the term of military service compulsory on every Frenchman, and so contain none of the callow youths which the exigencies of recruiting compel us sometimes to send to India, and though probably a distinctly younger body of men than our British colonial officials, will be, like them, men in the prime of life, and therefore fairly comparable, especially as the principal causes of death and invaliding are of a sort that attack all ages with tolerable uniformity. It is further to be noted that in addition to the sickness indicated above, all of which was of a serious character, a very large number of men, equivalent to 306·9 per thousand of strength, were treated for slight ailments "à la chambre." Against the comparative youth of the Frenchmen, too, may be placed the fact that like "Tommy Atkins," "Piou piou" is

probably a less careful person than civilians of good social position.

In the same year (1903) the mortality, &c., of Europeans on the British Gold Coast was returned as below :—

How Employed	Number	Deaths	Invalided	Death-rate per 1,000	Invaliding rate per 1,000
Officials	326	5	25	15·3	76·7
Mercantile Firms, &c. ..	335	12	18	35·8	53·7
Mining Companies ..	1,043	20	92	19·2	88·2
Missions	92	2	2	21·7	21·7
Totals	1,796	39	137	21·7	76·3

By a curious coincidence the total number of the two populations compared differs but little, and the mortality per thousand coincides almost exactly. The French invaliding is, however, more than double of ours.

A further point worthy of note is that however insalubrious a place must be where men are under medical treatment for ailments, great and small, four times in the year, the West Coast is almost a sanitorium compared with Cochin China, with a mortality of 33 and an invaliding roll of 205·5 per thousand, and is distinctly better than Tonquin. Now, the French Possessions in the Malay Peninsula actually march with ours in Upper Burmah, and it is hardly likely that the frontier that divides our possessions demarks any particular difference of insalubrity.

Most medical men who have practised in the East know that storax (*silaras*) is regarded as a most potent drug by the kaids and haqims, but few would be prepared to hear that India imports thirty tons of it annually, or that it is of sufficient commercial importance to render the question of its adulteration desirable by a Government official. However, Mr. D. Hooper, of the Indian Museum, has taken up the matter, and has discovered by chemical analysis that a large quantity of the drug is adulterated with pine resin. A paper on the subject has lately appeared, giving the results of the investigation, and the *Statesman* understands that the attention of the authorities has been drawn to the subject, so that care might be exercised in the future to obtain supplies of storax from authentic sources.

The Bombay Census.

The municipal census calculations have not yet been completed, though promised for Saturday at noon. Roughly speaking the population is put at 960,000, an increase of 190,000 on 1901.—*Pioneer Mail*, February 16th, 1906.

From the same journal we extract the following report of a speech by Lord Lamington on the virtue of cleanliness. If all our Indian Administrators held as sound and practical views on sanitation as the Governor of Bombay there can be no doubt that the history of hygiene in India would be more satisfactory than it has been.

"*Bombay, February 8th.*

"His Excellency the Governor, speaking last night at the annual meeting of the Bombay Sanitary Association, said that that Society and the St. John Ambulance Association proceeded on nearly the same lines—one was to meet a sudden emergency and the other was to inculcate the principles of proper sanitation, so that the lives of people in a great city like Bombay might be better preserved. If I remember rightly, he continued, it was at a meeting two years ago that a speaker declared that we had awakened the 'hygienic conscience' of the people, and from what I have been able to see for myself since my advent in your midst this has been strictly borne out. I cannot see myself that the people themselves lack in cleanliness either in their own persons—I am talking generally—or in their houses; but every one ought to extend their horizon and recognise their obligations not only to themselves but also to their neighbours and by practising the virtue of cleanliness they not only benefit themselves but their neighbours and help to preserve public safety. Man does not live alone; he has work in co-operation with his neighbours. Our duty is to persuade them to keep the outside of their houses as clean as they keep their own particular room. There is another matter—that of better ventilation. To my mind, it is brought home to us day by day by the medical authorities in every country, in every part of the world, that you cannot have too much fresh air. It is most deplorable even when I go round my own lines in Government House to see how, after a certain hour every little window is barred and barricaded as though they expect an attack from a foreign enemy. There is no possibility of fresh air, and whatever germs there are in this vitiated room go on multiplying. There are two great principles in which the majority of people want educating. One is to keep the outside of their houses or chowls clean, and the second is not to be afraid of fresh air."

We also extract an article on Professor Klein's new prophylactic for plague, which is of interest as indicating the trend of expert opinion in India on the merits of the new agent as compared with that of Haffkine's, which has been so long in use in that country.

"Professor Klein's report to the Local Government Board on his new plague prophylactic was forwarded to one of the leading experts upon the subject, who writes as follows :—

"'The experiments at present recorded are neither sufficient nor complete enough for an opinion to be formed as to the ultimate utility of this vaccine. It seems, however, that the results of the experiments do not sufficiently warrant the claims to superiority in comparison with the vaccine prepared by Haffkine. There is no doubt that Haffkine's method of prophylaxis has had a considerable amount of success. The Indian Plague Commission reported favourably on this method, and it is generally admitted that inoculation of this vaccine diminishes the incidence of attacks of plague, and that the mortality among inoculated persons is considerably less than among those not treated. The question as to the duration of the protection afforded is difficult to decide. It is probably not less than three months. There are certain disadvantages in this method which have prejudiced many against its use. Protection is not conferred on those inoculated for some days after the treatment, and during this period there is an increased susceptibility to an attack of plague. Consequently there is doubt as to whether its use in the presence of an epidemic is advisable. The protection afforded is not always complete, and is of short duration. Thus, while this vaccine is a valuable means of protecting temporarily against plague.

it is not a method of much practical use in face of an epidemic of plague. It not infrequently occurs that after inoculation the individual suffers from severe symptoms somewhat resembling those of the disease itself.

"'The new prophylactic of Klein does not appear to solve any of the present difficulties. His material is highly toxic. Like most other vaccines, it contains the dead bacillary bodies and their toxins. It also contains many other unknown constituents, the result of the inflammatory reaction of the tissues. The immunity conferred by its application is doubtless principally due, as in the other vaccines, to the toxins and the dead bacilli. It has not yet been ascertained at what time after the inoculation the immunity is established, and for what period it persists. Klein found the immunity present one to thirteen weeks after inoculation, a time limit which is inferior to that established by Haffkine's vaccine. The possibility of standardising the prophylactic by injection into rats is of value, but it is equally possible to standardise Haffkine's vaccine by injection into the guinea-pig. The new method described by Professor Klein is doubtless a means of affording protection against an attack of plague, but until many more experiments are completed to establish the nature and extent of this immunity it is premature to claim superiority over the other existing methods of vaccination. It is not simply a question of obtaining a cheap, easily prepared material. To combat plague, especially under the conditions which exist in India, there has yet to be discovered either a serum with curative properties or a vaccine which will confer a rapidly established and durable immunity, and be attended with no danger to those treated.'"

It may be remembered that in our issue of February 15th we reproduced a letter to the *Pioneer* from a correspondent in the Punjab on the occasional poisonous effects of the stalks of the millet known as jowar, when used as fodder for cattle, the writer stating that the people believed the poisonous action to be due to the presence of "small worms." The *Pioneer Mail* of February 16th contains a second letter from a Burmese official, which shows that the same view is held by the natives of far-away Burmah. It is well known that many insects are poisonous, so that it is by no means impossible that the native agriculturists may be correct in their belief, and the question is certainly worthy of investigation by the economic entomologist, if India chances to possess such a functionary.

Cattle Feeding on Jowar Stalks.

"Sir,—With reference to your article on cattle being poisoned by eating jowar stalks in your issue of January 13th last, and a letter from 'W.' in your issue of January 18th on the same subject, the following may be of interest:—

"The Settlement Officer, Magwe District, Upper Burmah, in his Settlement Report, seasons 1897-1903, remarks: 'In years of drought, when the plant (*i.e.*, jowar) becomes stunted and dried up, the stalks are poisonous to animals, and cattle sometimes die from eating them. In this district (Pakkoka) jowar is one of the main crops, and, of course, jowar stalks are used as fodder. The Burmans here tell me that in years of drought, before the ear has unfolded itself, an insect gets into the stalk; while so inhabited the stalks are poisonous, and, if eaten by cattle or ponies, cause death within a few hours. The insect appears to leave the stalk when the "ear" opens, which it would naturally do, of course, on the cessation of the drought.'"

A New Journal for Tropical Veterinary Medicine.

As for many years past it has been felt that there existed a distinct want for a scientific publication dealing with veterinary pathology in the Tropics, certain officers of the Indian Civil Veterinary Department have undertaken the publication of a quarterly periodical entitled the *Journal of Tropical Veterinary Science*, the first issue of which, dated January, recently made its appearance. Each number will, as far as possible, consist of original articles of scientific interest, with the exception of such pages given up to reviews and extracts from current literature as may appear to demand attention. Each of the three Editors—Major H. T. Pease, the Principal of the Punjab Veterinary College, Captain Baldrey, the Professor of Sanitary Science at the same Institution, and Mr. R. E. Montgomery, I.C.V.D., who is now on special duty investigating camel diseases—contribute articles to the first number, while Professor A. Lingard, Imperial Bacteriologist to the Government of India, has two articles. The journal is published by Messrs. Thacker, Spink and Co., and is excellently got up, clearly printed and illustrated with plates and diagrams. The annual subscription, including postage, is Rs. 12.8.—*Pioneer Mail*, February 28th.

The Medical (Lucknow) College Fund.

At a largely attended meeting held here and presided over by Mr. H. M. R. Hopkins, I.C.S., Collector, Rs. 17,000 were subscribed on the spot towards the Memorial Medical College, Lucknow. The principal speakers were Mr. Hopkins, and Syed Alay Nabi, B.A., and Munshi Narayan Pershad, M.A., Vakils. More subscriptions are expected.

Plague Work at the Parel Laboratory, Bombay.

During the past eight months, the Health Department have been engaged in trapping, poisoning and collecting rats, with the result that over 30,000 rats have been collected and sent to the Parel Laboratory for bacteriological examination every month, the Plague Research Commission supervising the work there. The report on the result of the examination of each rat is sent daily to the Executive Health Officer. When a rat is found to be infected the house or gully where it was found is marked "P.R." with the date, so that the premises and neighbourhood may be under observation. The Plague Commission are now working at Parel, and visit as many of the infected places as possible to collect material for their work. Cards are provided which are filled in by the district registrars giving information in detail about the rats and infected places, and the condition of the locality and its plague history. On an average, 1,100 rats have been examined daily at Parel, and the result sent at once to the Health Department. The proportion of infected rats recently increased from 2 to 20 per cent.—*Pioneer Mail*, March 28th, 1906.

Dr. Claus Schilling has been appointed head of the newly founded department of tropical diseases and hygiene established in Berlin in connection with the Institute of Infectious Diseases.

Seismic disturbances and prolonged drought have prevailed in several of the West Indian Islands;

St. Lucia and St. Vincent have suffered from severe earthquakes, and drought has been especially prevalent in Barbados, British Guiana, Grenada, and Trinidad.

THE PREVENTION OF YELLOW FEVER.

The Colonial Office authorities have issued a concise, practical, and clearly written eight-page pamphlet on "The Prevention of Yellow Fever." The general directions are based upon the assumption that "yellow fever can be absolutely suppressed by the application of simple, practicable, and non-costly methods," devoted to the prevention of infection of human beings by the bites of the Stegomyia mosquito. The pamphlet is illustrated by drawings of the *Stegomyia fasciata* and of the larvæ of Stegomyia.

His Excellency the Governor-General of the Sudan has directed that a Commission be appointed to investigate the possibility of the extension of "sleeping sickness" into Sudan territory. The Commission to be as follows: Lieut.-Colonel G. D. Hunter, D.S.O., P.M.O.E.A; Dr. Andrew Balfour, Director Wellcome Research Laboratories, Khartoum; a British medical officer, Egyptian Army, or medical inspector, Sudan Medical Department, or such members as may be hereafter appointed.

Points to be Investigated.

(1) To ascertain the distribution of various species of tsetse-flies or other biting flies in the Sudan.

(2) To ascertain if the disease at present exists in Sudan territory. If so, to determine the exact areas, and to what extent the distribution of the disease coincides with the presence of the tsetse or other flies in these areas.

(3) A systematic investigation of the blood of a population in an infected district.

(4) A thorough and complete research into the character of the disease, especially as regards its origin and spread.

DEATH OF A POPULAR DOCTOR.

The death took place, on the night of the 21st inst., of Rai Bahadur Doctor Ram Lal Chuckerburty, who, for more than a quarter of a century, was one of the leading medical practitioners in Oudh. He was much beloved, admired, and trusted by all communities. He succumbed to an attack of plague, after suffering for six days. His age was 65. He leaves behind him a widow, three sons, and three daughters. His remains were carried in a special train to Cawnpore for cremation on the banks of the Ganges.—*Pioneer Mail.*

The University of Allahabad has been directed by the Government of the United Provinces Agra and Oudh to consider the question of forming a faculty of medicine.

The Government of Bombay has appointed a mixed committee, under the presidency of the Surgeon-General with Government of Bombay (Civil Department), to investigate the prevalence of malarial and other fevers in the city. According to municipal statistics the deaths from these causes have varied from 7,513 in 1880 to 2,333 in 1903.

Personal Notes.

R.A.M.C.

The following officers of the R.A.M.C. are to command the Station Hospitals named: Lieutenant-Colonel S. G. Allen, Kalabagh; Lieutenant-Colonel R. G. Hanley, Kaldanna; Major O. R. A. Julian, C.M.G., Cherat; Major R. Holyoake, Solon; Major G. Scott, Gharial; Major T. W. Gibbard, Barian Camp; Captain F. S. Walker, Khyra Gali and medical charge of the School of Musketry, Changla Gali; Captain H. W. Long, Upper Topa; Lieutenant J. A. Turnbull, Khanspur; Lieutenant A. W. Gater, Ghora Dhaka: Lieutenant S. M. W. Meadows, Cliffden; Lieutenant R. H. L. Corduer, Hara Gali; Lieutenant H. T. M. Wilson, Lower Topa.

INDIAN MEDICAL SERVICE.

India Office: Arrivals, &c., of Medical Officers; Reported in London during April.—Lieutenant-Colonel J. B. Gibbons, Captain J. B. Christian, Captain S. Evans, Captain L. Reynolds, Captain A. W. C. Young, Lieutenant-Colonel R. H. Charles, Lieutenant-Colonel P. D. Pank, Major L. F. Childe, Major F. G. Maidment, Captain H. M. Cruddas, Captain H. W. Illius, Captain F. N. White, Lieutenant G. F. Harkness.

Nursing Sisters.—Miss B. Crane, Miss D. L. T. Moore.

Extensions of Leave.—Major H. E. Drake Brockman, 6 m.; Captain W. Lapsley, 3 m.; Professor Haffkine, 6 m.; Major J. G. Jordan, study leave, 3 m. 25 d.; Major H. Austin-Smith, study leave, 1 m.; Major G. F. W. Ewens, study leave, 8 m.; Captain R. E. J. Lester, 5 m.; Major E. V. Hugo, to July 2nd; Major J. Stodart, 5 d.; Captain H. H. Brown, 6 m.

Permitted to Return to Duty.—Captain V. B. Bennett, Lieutenant E. C. Hodgson, Major E. Hugo, Lieutenant-Colonel J. A. Cunningham, Major J. Stodart, Surgeon-General W. L. Gubbins, A.M.S.

Postings.

Captain Battye, I.M.S., acts as Consul-General, Meshed, during the absence of Major Sykes, I.S.C.

Major Duke, Civil Surgeon, Bikanir.

Major Robinson, Residency Surgeon, Jaipur.

Major G. B. Hunter, services lent, Punjab Jail Department.

Lieutenant-Colonel R. E. S. Davis officiates as Inspector-General, Prisons, Burmah.

Major J. P. Penny officiates as Civil Surgeon, Rangoon.

Captain E. R. Rost to charge of Plague Hospital, Rangoon.

Captain W. V. Coppinger officiates as Civil Surgeon, Mymensingh.

Lieutenant A. D. White holds additional Civil Medical Charge of Buxa Duar.

Lieutenant-Colonel W. A. Quaile, Civil Surgeon, Jubbulpur.

Major A. G. Hendley, Civil Surgeon and Superintendent Jail, Sangor.

Major B. R. Chatterton officiates as Surgeon Superintendent, Presidency, General Hospital, Calcutta.

Major J. G. Gordon, Civil Surgeon, Chittagong.

Captain C. G. Seymour officiates as Civil Surgeon, Cachar.

Major D. R. Green, Civil Surgeon, Khasi and Jantia Hills.

Major C. Milne, Civil Surgeon, Fyzabad.

Lieutenant-Colonel T. R. Mulroney, Civil Surgeon, Karnal.

Captain T. G. Stokes, for the season to Pachmari.

Captain C. G. Seymour to Civil employ, Eastern Bengal and Assam (temporary).

Major Bird officiates as Professor of Surgery, Calcutta.

Captain J. R. Tyrell has been placed on plague duty in Ajmir-Merwara.

Captain E. D. Greig has been placed on special duty in Central Research Laboratory, Kasauli.

The following I.M.S. officers have been granted leave:—

Major R. G. Turner (furlough, privilege, and study leave), 17 m. 17 d., from April 10th.

Major J. Chaylor White (privilege and urgent private), 6 m., from March 30th.

Major G. M. Smith (privilege and furlough), 16 m.

Lieutenant-Colonel J. R. Adie (study), 6 m.

Lieutenant-Colonel Charles, Professor Surgery, Calcutta, furlough, 12 m.

Major Green, Civil Surgeon, Muzaffarpur (furlough), 2 y.

Captain A. Moorhead (combined leave), 8 m.

Captain H. Illius (general leave in India), 1 y.

Captain Wilson (combined and study), 18 m.

Captain H. Hamilton, C.B. (privilege leave), 90 d.
Captain A. Leventon (combined leave), 20 m. 18 d.
Major C. R. M. Green (combined leave), 2 y.
Major G. W. F. Braide (combined leave), 7 m.
Captain R. P. Wilson (combined and study leave), 18 m.
I.M.S. Retirements. — Lieutenant-Colonel Banerjee, Lieutenant-Colonel J. A. Dalal, Lieutenant-Colonel H. Mariett.

Prescriptions.

FOR FACIAL NEURALGIA.

℞ Butyl-chloral	...	...	gr. 3 to 5.
Tinct. gelsemium	...	...	♏ 5 to 10.
Glycerini	...	...	♏ xxx.
Aq. anethi	...	...	ad ʒss.

For one dose. Repeat at required intervals. (Suggested by W. H. Wynn.)

TO PREVENT INTESTINAL FERMENTATION.

℞. Careful dieting, and calomel thrice daily in doses of $\frac{1}{40}$ to $\frac{1}{20}$ grain. (W. H. Wynn.)

ACUTE DYSENTERY.

R. J. Windle recommends :—

No. 1.

℞ Chloral hydrat.	...	...	grs. xx.-xxx.
Liq. opii. sed.	...	...	♏xx.
Aq. ad.	...	...	ʒi.
Syrup. aurant.	...	...	ʒii.

No. 2.

℞ Pulv. ipecac.	...	...	grs. xx.-xxx.
Aq. chloroformi	...	...	ʒi.
Mucilag. tragacanth.		...	q. s.

No. 2 is given ten to fifteen minutes after No. 1.

URTICARIA.

To allay itching apply :—

℞ Acid. thymic	...	...	grs. xv.
Acid. carbolic	...	...	grs. xxx.
Menthol	...	...	grs. iv.
Eau de Cologne Sp. camphor	...	...	āā ʒ iijss.

—*Progrès Médical.*

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Münchener Med. Wochenshrift," January 2, 1906.

Although antivenin is always used in Austria in cases of snake-bites by vipers, in Austria a ready means of treatment is described as follows: Application of a tourniquet, an elastic constriction is applied on the proximal side of the bite, and 20 cc. to 30 cc. of a 1 in 22 solution of chlorinated lime in water is injected into and round the seat of the bite. This treatment seems to be efficacious.

"Journal American Med. Association," March 10, 1906.

THE DIBOTHRIOCEPHALUS LATUS (THE BROAD TAPEWORM IN MINNESOTA, U.S.A.)

Nickerson, S. D., reports a case of infection by the broad tapeworm, occurring in a patient resident in Minnesota. Hitherto such cases were believed to be importations from Northern Europe, and the case described by Nickerson was in a child of 3 years of age, born in Minnesota of Finnish parents, of whom the father was known to have suffered from the worm.

Infection by the broad tapeworm occurs through the injection of the larvæ (plerocercoid) embedded in the flesh of certain fresh-water fishes. As fresh-water fish are not imported into America from Finland, the conclusion seems to be that some native American fish must harbour the larvæ. Moreover, it has been proved that infection of American fish by the larvæ of Dibothriocephalus is possible, and it only requires the arrival of an infected adult population from districts (Finland, Scandinavia, Poland or North Germany) where the disease is prevalent, to understand how the eggs and larvæ can travel by the sewers into inland fresh-water lakes or streams, and so infect the fish. As however, it is only when fresh-water fish are eaten raw, or partially cooked, that the disease can be conveyed, it is difficult to understand how human beings become infected, although domestic animals, such as cats and dogs, would be liable to harbour the parasite.

"Le Caducée," March 3, 1906.

"Cutaneous Eruptions of Malarial Origin, and What they Foretell" (Les éruptions cutanées du paludisme ; conséquences à en tirer au point de vue des manifestations de cette affection). By Surgeon-Major Claude.

As in the case of the majority of intoxications and of general diseases, malaria has also its cutaneous manifestations. Dr. Billet was one of the first to describe them, and as his observations on malarial febrile erythema were all supported by an analysis of the blood of the patients their origin is undeniable. Dr. Coste, who is in charge of the military hospital at Arzew, has also quite recently made a study of the cases of dermatitis of malarial origin which absolutely resemble, by their eruptive characteristics, the rash of measles. Malarial urticaria has been noted by Lespinasse in the Sudan; Vacari has also observed several forms of it.

Surgeon-General Moty attributes to malarial infection certain cases of cutaneous gangrene, closely allied to urticaria, which he accounts for as follows: Obstruction of the capillaries by pigmented leucocytes, want of nutrition induced thereby, and necrosis of the tissues.

An analysis of the blood should always, therefore, be made to confirm the truth of their malarial origin, but this for many reasons is not always practicable in malarial climates ; microscopes are not always ready to hand, and their carriage offers many difficulties. In any case, cutaneous manifestations, generally of a febrile character, should always, when they occur in a tropical or marshy district, be considered as possibly malarial in origin. But we, for our own part, are of an opinion that they have also an importance as forerunners of further phenomena ; they may, indeed, be premonitory of a severe, and even very dangerous, attack of acute malaria ; in chronic malaria, on the other hand, the eruptions seem to foretell, at an early date, a return of a true febrile attack, similar in all respects to the acute form of ague.

The following notes leave no doubt in this respect; they have been condensed, and only the main facts are here recorded :—

(1) Mrs. X., a recent arrival at S., a very malarial spot in the province of Oran, was laid up in August, 1904, with an acute attack of ague. One of these attacks was accompanied by an erythematous eruption over the body generally, extending in patches even to the face ; the fever subsequently took on a continued type. Suddenly, attacks of hæmoglobinuria developed, the eruption disappeared, and death took place on the fifth day.

(2) Zouave, N., stationed at S. for several months, has never had ague ; in September, 1903, he was admitted to hospital with acute malaria. Whilst in hospital he developed shingles on the left side of his chest. The next day he was seized with a pernicious attack. The patient died in a few hours, in spite of injections of quinine, &c.

(3) S. (of Spanish extraction) was admitted to hospital at

Daya in August, 1903, with acute ague. During an attack an erythematous rash appeared on his trunk and face. As delirium set in, he was taken back to his house by his friends. The eruption ceased the same day that he returned. The patient died the next day in convulsions in spite of all care.

The rapidity with which all these three cases of cutaneous manifestations were followed by a fatal termination is truly worthy of note. Fortunately, in chronic malarial patients the eruptive manifestations do not appear to be of such serious import; this statement is borne out by the following cases :—

(1) X., an army surgeon, since his return to France from Algeria, has suffered from several malarial attacks, which were more frequent than when he was abroad; at times he suffers from a severe pain in the regions of the left brachial and cervical plexuses. One evening he was suddenly seized with an attack of urticarial eruption, limited to both hands and both forearms; there was an unbearable itching for two days, then the uticarial rash disappeared, but the patches of skin seemed as if wine-stained. All these symptoms disappeared, but X. was seized with a true fit of ague, with all its three stages. Three months later the same symptoms were repeated in an identical manner. Quinine had but little effect either on the rash or the attacks of ague which followed them.

(2) Captain N., of the 3rd Zouaves, stationed in France for the last year, was seized one evening in March, 1905, with general prurigo, also with urticarial patches on the upper limbs and on the neck. He consulted the surgeon on duty and informed him that, in consequence of this manifestation, he would suffer in a few hours from a long and sharp attack of ague. True enough, ten hours later the premonitory rigor commenced. The attack was followed by prostration which lasted four days. This officer stated that this was always the case after the urticarial attacks, whilst when there was no eruption he was always able to return to his work immediately after the ague fit was over.

(3 and 4) Two similar cases to the above in non-commissioned officers were also recorded; these were both old malarial subjects.

It would, therefore appear that the following conclusions may be applicable in all cases of malarial intoxication of whatever date :—

(1) All cutaneous manifestations occurring in a malarial subject would appear to foretell a more or less serious relapse.

(2) With a view to meeting the gravity of this relapse, all therapeutical means should be employed immediately on the onset of the eruption, although in all our own cases they appeared to us to be of little effect; but further trials might be made in this respect.

"Verhandlungen der Deutsch. Zoolog. Gesellschaft," 1905, p. 16.

ON THE FECUNDATION OF THE PROTOZOA.

Schaudinn emphasises the modern view of the nuclear dimorphism of these organisms, concluding that "in all protozoa, whose cycle of evolution and fecundation is known, a dualism of the somatic and reproductive nuclear constituents may be recognised at some stage of development." Applying these ideas to the complicated structure of trypanosomes, and especially to that of *Trypanosoma noctuæ*, he identifies the flagellar apparatus of a trypanosome as equivalent to the macro-nucleus or vegetative nucleus of an infusorian, but does not include the smaller nucleus or blepheroplast with the flagellum in this homology.

The two chromatin masses of the trypanosome, *i.e.*, the nucleus proper and the blepheroplast, are for him the equivalent of the infusorian micro-nucleus, both being, he points out, mainly formed of reproductive elements. In the process of evolution, the large nucleus throws off its vegetative elements in the form of chromatin, while the small nucleus develops the locomotive apparatus, so that the two combined represent the primitive element of the infusorian; and Schaudinn concludes that the trypanosomes exhibit a double nuclear dimorphism.

It may be remembered that Schaudinn divides the oökinets of *Halteridiun noctuæ*, which develop in the mosquito into trypanosomes, into male, female, and indifferent forms. The female forms are large with a big nucleus, and the locomotive apparatus and blepheroplast but little developed. The male forms, on the other hand, are small with small nucleus, and large locomotive parts and blepheroplast. He thinks, therefore, that the large nucleus contains mainly male, and the blepheroplast female elements.

This sexual distinction originates in the earliest development of the oökinets. In all there is a division of the nucleus of copulation into a large and small nucleus, the former aborting in the males, and the latter in the females, while in the intermediate forms both persist. He emphasises the peculiarities of copulation in *T. noctuæ*—quantitative and qualitative nuclear reduction (expulsion of male and female substances, and reduction of the number of chromosomes to one-half; persistence of male and female centrosomes; and independent unions, two and two of the male nuclear elements of the male with the female nuclear elements of the female.—(Trans. of F. Mesnil's abstract in the *Bulletin de l'Institut Pasteur.*)

FISH PARASITES.

Johnstone, J., describes a considerable number of trematodes, cestodes, an *echinorhynchus* and a sporozoan from a number of common edible fishes, and his paper has necessarily a comparative interest for all engaged in the study of helminthology.

"Atti. R. Accad. Lincei de Roma," 1905, p. 411.

CUTANEOUS INFECTION BY ANCHYLOSTOMUM.

Pieri, Leno, concludes that man is infected either by swallowing the mature larvæ of (or by penetrating the skin) the *Uncinaria americana* as well as *U. duodenalis*, being both capable of infecting man by either route. The same remark applies also to *Dochmius trigonocephalus* and *D. stenocephalus* of the dog, but in this animal infection by penetration of the skin is the more efficient route of infection.

"C. B. Acad. des Sciences," cxii., p. 1204.

IDENTITY OF SURRA AND MBORI.

Laveran, Prof. Experiments conducted by Vallée and Panisset show that bovines immune to the surra of Mauritius are also so against mbori, the trypanosomiasis of dromedaries in Timbuctoo. M. Laveran now shows that, conversely, a goat immune to mbori is also so to Mauritius surra, thus placing the identity of these diseases beyond question.

"Centralblatt f. Bakter.," I., Origin, 1905, p. 43.

SPREAD OF PLAGUE THROUGH THE AGENCY OF INSECTS.

Hunter, W., of Hong Kong, points out that insects have long been suspected as possible vehicles of plague infection. For example, in 1498, Archbishop Knud wrote that the approach of plague is heralded by a change of weather with thick fogs and the appearance of swarms of flies. He discusses at length the potentialities of flies, mosquitoes, lice, fleas, and cockroaches in this respect, and the organs of these insects in which the virus may be carried; and the mechanism of infection by the fouling of clothing, food, &c., or by biting. His conclusion is that insects are actually capable of transporting plague to long distances, but that there is little to choose between biting and non-biting insects in this connection, as he believes that the danger of bites from insects that have been on plague patients is greatly exaggerated, and that the really important point is that many insects are capable of infecting food, clothing, and furniture of all sorts.

EXPERIMENTS ON THE TREATMENT OF TRYPANOSOMIASIS BY MEANS OF ANILINE COLOURS.

These experiments form the subject of an inaugural dissertation by Ewald Franke, and were conducted under the superintendence of Prof. Erlich, who himself, in conjunction with Shiga, had already made some experiments with a a dye called trypanroth. An injection of this dye appears to cure mice infected with "caderas," and Franke now finds that immunity lasts for twenty-one days after the cure. Neither malachite green nor ethyl green proved as effective as trypanroth. Even better, is a combination of arsenic and trypanroth suggested by Laveran.

Franke also cured a monkey (*Cercopithecus callitrichus*) by a combination of arsenic and another dye which he merely speaks of as being "near" trypanroth. The serum of this monkey was also proved to possess parasiticide and agglutinating powers.

"Indian Medical Gazette," April, 1906.

TEN DAYS' PIGMENTARY FEVER OF BENGAL.

Cobb, Lieut.-Colonel R., says: This form of the indeterminate fever of India occurs during the hotter part of the year, and is characterised by "continued fever," lasting from eight to ten days, and the presence of a peculiar pigmentation of the face which follows the febrile attack. It usually seems to occur in persons who have been exposed to great heat, and the onset appears to closely resemble an attack of influenza, apart from the more usual catarrhal symptoms of the latter. The pigmentation is "bat-shaped," taking the same form as the eruption of lupus erythematous. No parasites are found in the blood, nor is the liver or spleen affected. A detailed account of a typical case and short notes of twenty-nine others are given by way of illustration.

This is an interesting instance of the differentiation of a class of cases that undoubtedly, till lately, would have been put down to the credit, or rather discredit, of malaria.

"Bull. de l'Institut Pasteur," T. 4, p. 241.

Summary of papers presented to the Annual Meeting of the Society of American Bacteriologists at the University of Michigan.

Norris, Pappenheimer and Flourney, preliminary communication on the infection of white rats with spirochætes, and on the multiplication of the latter in a liquid medium.

With the blood of a case of relapsing fever they succeeded in infecting both monkeys and white rats. The latter when infected by subcutaneous inoculation showed more or less numerous spirochætes in their peripheral blood for the next two or three days, and these persisted from one to three days. Beyond splenic engorgement, the rats did not seem ill, and there were no relapses. They succeeded in as many as twenty-five serial infections, and the infected rats acquired immunity, but though their serum, mixed with infective blood, retarded the evolution of the spirochætes, it was useless when injected a few days before. The authors observed nothing indicative of longitudinal division, and believe that proliferation takes place transversely, and that the spirochætes are really nearer to the bacteria than to the protozoa; nor could they find any sign of either cilia or undulating membrane. The spirochætes in a small quantity of infective blood added to citrated human or rat blood multiplied considerably, and this could be repeated once, but no more. Citrated infective blood retained its infectivity for six hours at the temperature of the laboratory.

TRYPANOSOMES OF MOSQUITOES.

Novy, F. G., MacNeal, W. J., and Torrey, H. N., of the University of Michigan. As the result of their work on the cultivation of the trypanosomes of birds, the authors maintain that the flagellates observed by Schaudinn in mosquitoes are not, as the latter thinks, evolutionary stages of the endoglobular parasites of the birds, but cultivations *in vivo* of trypanosomes present in the blood of the birds experimented with. They, therefore, try to show that trypanosomata can live and multiply in the intestine of mosquitoes under forms corresponding with those which can be got *in vitro*.

Mosquitoes (800) were caught and fed on animals ascertained to be free from hæmatozoa. The intestines of 15 per cent. of the mosquitoes contained flagellates, the lumen of the intestine in some being quite obstructed with masses of rosettes of flagellates with the flagellæ in the centre. Several different trypanosomes were found, *Crithidia fasiculata* and a form perhaps identical with *Herpetomonas subulata* being the commonest. Owing to the presence of bacteria, cultivation of these flagellates was difficult, but the *Herpetomonas* was isolated in company with a small coccus and the *Crithedia* together with a yeast; and these cultivations remained for six months in the laboratory, while in the others the flagellates were crowded out by the bacteria. These cultural forms are identical with those of the mosquitoes, *e.g.*, the blepheroplast is always in front of the nucleus and, under both conditions, the *Herpetomonas* has two characteristic diplosomes in the hinder part of the body.

The results of inoculations of animals with the cultures were negative. When mosquitoes are fed with *Trypanosoma brucei* or *T. lewisi*, these parasites persist for more than twenty-four hours in the intestine of the mosquito, and retain their infectiveness for rats. The authors believe, therefore, that the trypanosomes found in the stomachs of tsetse-flies, fleas, &c., are really cultural forms, the blepheroplast being in front of the nucleus. They conclude, therefore: (1) That these forms can be cultivated in test tubes; (2) that the herpetonads found in flies and mosquitoes are really cultural trypanosomes, and that further researches will demonstrate the hæmatozoa, from which they originate; (3) The *Crithidia*, on the other hand, have no undulatory membrane, and for the present may be taken to represent a distinct genus.

Novy, E. G., and Knapp, R. S., describe a method of isolating trypanosomes from accompanying bacteria.

"Ann. Inst. Pasteur," December 12, 1905.

Emile-Weill, P., details various attempts to cultivate the *Bacillus lepræ* in a variety of media, and comes to the conclusion that success depends on the presence of human tissue elements included in the leproma, as in only two instances of cultivations on yolk of egg did the bacilli survive after having digested those cells.

"C. R. Soc. Biologie," T. lx., p. 291.

Sergerit, Edm. and Et., describe, under the name *Herpetomonas algeriense*, a flagellate often found in the intestine of *Culex pipiens* and *Stegomyia fasciata*, bred in the laboratory at Algiers. In its motile form it has an elongated, pyriform body, with a flagellum, which arises from a centrosome placed behind the nucleus. Besides these there are spherical motionless forms with long flagella.

Besides these they have found in an old preparation made in 1901 from the intestine of *Anopheles maculipennis* another flagellate, with a very long fusiform body, pointed behind and rounded in front, with a long lash, which resembles *Herpetomonas jaculum*, discovered by Leger. The same preparation also contained a number of spirochætes.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the JOURNAL OF TROPICAL MEDICINE should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communications.

THE PURU OF THE MALAY PENINSULA.

By T. D. GIMLETTE, M.D.

Awarded a Craggs' Research Prize, 1905,

London School of Tropical Medicine.

A DISEASE known by the Malay name of puru has never been described in detail from the Malay Native States before, and although it is very common among Malays, nearly all our information concerning it has hitherto come from the group of islands which forms the Malay Archipelago.

This wholly unmerited neglect by residents on the mainland in the description of puru has probably been partly due to the tardy exploration of this part of Further India, which was only commenced lately [1], partly to the natural reticence of the natives and the suspicion with which the Malay peasantry regarded the prying eye of Western medical science, but chiefly to want of independent medical observers with time and opportunity for special investigation.

Until quite recently the prevalence of puru in British Malaya seems to have even escaped the attention of the Federated Malay States Government, but this, again, is probably owing to the fact that the disease does not interfere much with labour, which is mainly carried on by Chinese, and, speaking generally, because it does not permanently injure the health of the Malay to any extent. The natural tendency of the disease is towards spontaneous cure. Death from puru is unusual; it is seldom fatal, unless during very early childhood or in advanced old age.

A period of seven years' service in the Government of the Federated Malay States, spent in the States of Pahang, Selangor, and Perak, has given me experience of puru, and a further residence of over two years in Kelantan, a Malay State hitherto unexplored by students of tropical medicine, and one in which this disease is most prevalent, has afforded me an unusual opportunity for observing it under purely native conditions. My contention is that the puru of the Malay peninsula is identical with the West Indian and African yaws and the Fijian coko, and that it has no real relationship with syphilis.

THE HISTORY OF PURU.

The earliest references which can be taken as bearing upon puru are by Bontius in 1718, who seems to have recognised it in the Molucca Islands as the amboina pocks [2], and by Marsden, who mentioned a native disease called nambi in his "History of Sumatra" (1811) [3].

Many years later, Charlouis, who described frambœsia from Java as polypapilloma tropicum [4], gave one of the local native names as nambie. But up till now (1886) even Hirsch had been led from want of records to assume that the mainland of Further India had been little, if at all, visited by frambœsia or yaws [5]. Ten years later a definite outbreak was reported from Assam [6], and yaws has quite recently been described as being very common in Siam [7].

In 1893, Dr. Brown described puru from Penang as lupus contagiosus malayorum [8], and in an annotation on this important paper, Dr. T. Colcott Fox drew attention to the similarity of puru to yaws, but finally concluded that puru was the same as Oriental sore, and in 1897 the name was given as a synonym of that disease in Allbutt's "System of Medicine" [9]. It has since been shown that the appearance of some true Oriental or Delhi sores is by no means so characteristic as one would expect it to be from descriptions given in books [10].

Dr. Barker, of the Sarawak Civil Service, was the first to identify puru with yaws from Kuching in 1898 [11], and Dr. Connolly, of the Federated Malay States Civil Service, wrote a valuable memorandum in the same year, on the occurrence of yaws in Kinta, a district in the Federated Malay States [12]. Puru is given as a synonym of yaws in Scheube's "Diseases of Warm Countries" [19] (1903), and Dr. George Pernet (1904) has mentioned the puru of the Malay States under the heading of yaws [13], as well as Dr. C. W. Daniels, the Director, Institute for Medical Research, Federated Malay States, who has included it among the commoner diseases of Malays [14]; but with these important exceptions there are few, if any, direct references to the prevalence of the disease in the Malay peninsula.

THE ETIOLOGY OF PURU.

The true infective agent of the disease has not yet been recognised, and in a review of the etiology of puru, little or no support can be relied upon from any in-patient hospital statistics. Cases either under the name of puru or of yaws are seldom included in the returns of the Federated Malay States hospitals. The reason is that although the Malay native attends readily as an out-patient at any convenient and charitable dispensary, or possibly clamours for medicine on the visit of a European to his village, yet, notwithstanding the many opportunities for further improvement offered by European hospital treatment, the peasant fails to this day to be attracted by the benefit of treatment in a hospital ward, and generally applies for admission in a spirit of tolerant curiosity and in a desultory fashion, which is merely the effect of a momentary enthusiasm or the result of a personal attachment.

Under these circumstances it is impossible to collect hospital statistics which are of any great value. There is no medical literature. The only knowledge is that of the individual. The Malay medicine man (bomor) and the witch doctor (pawang) is for the most part but a native magician or a veteran wiseacre. They say naively that puru (literally a sore), like small-pox, comes from the smoke of hell fire! I have obtained, however, a good deal of general information from these native physicians.

Age.—Puru is one of the most common diseases of Malay children, but it is rare among infants; and it is, I think, seldom seen as early as the eighth month of life.

It is common to find puru in almost any Malay village (kampong) among little children who—although probably still at the breast—are able to walk alone and are exposed to contagion. The disease is not, however, confined to children, and may occur at any

age, except at birth. Out of fifty individual cases noted in the out-patient registers of the Duff Development Company's hospital at Kuala Lebir in the interior of Kelantan (from July, 1903, to July, 1905), twenty-four were children whose ages ranged from four to twelve years. The others were all adults who applied for relief mostly during the first year of the establishment of the hospital (1903), suffering from the later manifestations of puru of the foot.

Sex.—Puru appears to attack either sex with equal frequency, but in adults lesions of the foot are more common among males.

There is a variety called puru kochi (literally, Cochin China sore), which is said by Malays to attack the genital organs only, and to be more common among the female sex, but not necessarily confined to women. Dr. C. W. Daniels has suggested to me the possibility of puru kochi being akin to sclerotising granuloma of the pudenda. It is rare, and has not yet come under my personal observation.

Race.—The permanent native population suffers out of all proportion to the many inhabitants of the native states of the Malay peninsula. It is no exaggeration to say that at least 90 per cent. of the Malays in Kelantan are attacked by puru. Europeans appear to be exempt, but I have seen it among Chinese, Javanese, Siamese, and more rarely in Sikh and Dyak settlers. In the Federated Malay States it appears to me to be uncommon among Tamil immigrant children. I have seen it among the wild aboriginal inhabitants (Sakui-Semang) of Kelantan. It is common among them, and in the Kuala Lebir district is known in their dialect by the name of "choh."

Heredity. — In this disease heredity has apparently no influence. Children are never born with puru, even if one or both of their parents suffer from the disease at the same time. Puru is never seen during the forty days of the Malay puerperal state. There is no evidence, in fact, of congenital puru among Malays, who hold that the disease is always acquired. Abortions as the result of puru are almost unknown, unless during a very severe attack. Intermarriage and consanguinity do not seem to have any influence. Among hereditary antecedents there are no diseases from which Malays commonly suffer which seem to have any relation to the etiology. Tuberculosis is, I think, on the whole, as infrequent as leprosy among the country people. Lupus appears to be unusual in the Federated Malay States.

Physical Geography.— The Malay peninsula lies between the Straits of Malacca on the west and the China Sea on the east. It is made up of a number of native states, which are divided into eastern and western by a range of mountains which runs like a backbone nearly through its entire length. The height of the various peaks of the range varies from 3,000 to over 7,000 feet above sea-level.

The most important of these states are under British protection. They are the States of Perak, Selangor, Pahang, and Negri Sembilan, which were confederated in 1897, and have since been known as the Federated Malay States. They are situated in the centre of the Malay peninsula, and are bounded on the north and north-east by Province Wellesley and the Malay States of Kedah, Patani, Kelantan, and Trengganu; on the south by Malacca and the State of Johore; and on the east and west by the China Sea and the Straits of Malacca respectively.

The population of the Federated Malay States numbers approximately 665,000 persons.

Kelantan is the most important of the other Malay states. It approaches Siam, being between lat. 5° 40′, and 6° 20′, north. It is bounded on the north by the Malay Straits of Legeh and Patani—dependencies of Siam adjoining Singgora, the southernmost point of the kingdom of Siam.

Climate.—The Malay climate is hot, moist, and very equable, making the peninsula a hotbed for fostering parasitic diseases of the skin, especially tinea imbricata, which is indigenous among many others. The average mean temperature in the shade may be said to be—maximum from 85·0° F. to 88·0° F., and minimum from 70·0° F. to 72·0° F. The highest maximum may be taken at 96·0° F., and the lowest at 68·0° F. The rainfall is large ; over 100 inches per annum is the rule in most Malay states. Any division between wet and dry seasons for the year is very indefinite.

Geographical Extension.—As regards the Malay peninsula, puru is probably universal, although it may be more common in some places than in others. It occurs in all the states of the Federation, especially in Pahang, and is very prevalent in Kedah and Kelantan. It has been observed as far north as Legeh and Patani. In Trengganu puru is said to be even more abhorred than small-pox, on account of its persistent and chronic nature.

Hygiene.—The personal hygiene of the Malays is good. Country people bathe at least twice a day, but there is often much to be desired in the cleanliness of their attire. Children at the age at which puru is common wear little or no clothing.

Social position has probably no influence at all as a predisposing cause of puru among Malays. In Kelantan it is as common in the dwellings which form the native palaces as among the cluster of huts which make up the smallest hamlets. His Highness the Rajah of Kelantan, for example, has suffered from puru as a child, and the princes frequently contract puru.

The hygienic conditions of Malay life are similar, however, both in the high-born and in the low-born native as regards house accommodation. The sanitary condition of nearly all their houses is bad, and, although they are raised from the ground, they are ill-drained, ill-lighted, ill-ventilated and ill-cleaned. The daily household slops (mostly dirty liquid refuse from cooking) are thrown through loose bamboo floorings and allowed to soak into the ground beneath, so as to form a permanent slush under the kitchens. On the other hand, in the rural districts, where for the most part puru is very prevalent, it is very often common for natives to dwell upon bamboo rafts, which are made in the form of house-boats. The mass of the Malays, in fact, live either on rafts or in comparatively small huts built along the banks of the rivers. The Malay states are well watered by innumerable rivers and streams, and it is fortunately seldom necessary, therefore, to store water in this part of the East.

The only instance of the bad effect of stored water

in the Federated Malay States is, I believe, an epidemic of zinc poisoning which occurred in Pahang in 1900 among a half company of Sikh soldiers, which might have been attributed to the climatic effect on the corrugated iron roof from which a supply of rain-water was derived [18].

Preceding Illness.—At first sight puru apparently possesses an analogy to syphilis, but it is never thought by Malays that there is any affinity between these two diseases. There are many specific characters by which to distinguish them. Neither is a protection from the other, nor do they vary in inverse ratio. It is only a previous attack of puru that protects the individual from a recurrence of puru.

It is fitting to mention here that—making due allowance for many errors in the definitions of Malay nosology—many of the manifestations of venereal disease, as it occurs among dark races in warm climates, are well known to Malays.

Gonorrhœa is generally known in Malay as sakit kenching (lit. sakit, sick, and kenching, urine), or as karang.

Venereal buboes are referred to in many states as mangga, which literally means a mango. Curiously enough, the Chinese also call them suai or mangoes. Syphilis is known in Kelantan as seduwan or seduwan sundal (seduwan, a bad disorder; sundal, a bare-faced harlot), or in other places as sakit prempuan (prem-puan, a woman). Three stages of seduwan sundal are recognised: (1) The original manifestation in man or woman on the genital organs; this is followed by (2) seduwan bunga (bunga, lit. a flower or pattern on anything), which attacks the gums and face, and is supposed by Malays to be due to infection (uwap, lit. vapour or steam); and (3) seduwan angin (angin, lit. wind), which especially affects the joints and bones.

The term stong or restang is commonly applied to destructive ulceration of the nose, such as occurs in tertiary syphilis. These diseases are all of common occurrence.

Other Observations and some Native Ideas.—The contagion of puru is well known. Malays say that children who play about together catch it from one another, but though two or more children in the same family may contract puru at the same time it does not necessarily run through the whole family. A second attack is said never to occur in the same person. Many hold that a kind of immunity is established in later life by the occurrence of the eruption in a rotation of three crops before the age of 3 years.

Isolation is never thought of, but natives avoid contact with the discharges of puru, and do not care to eat with people who may be afflicted with the general eruption. It is thought to be unwise to bathe immediately below any one suffering from puru of any kind, and many Malays are careful to bathe up stream, or away from people who are engaged in washing their sores or those of their sick children at the time.

Deliberate inoculation is never practised among them. The attack frequently follows on some slight scratch or abrasion, but it is said that the sores of the Malay kudis (lit. scurf), a kind of generic name given to ulcers as well as to scabies, or kudis gatal (gatal, to itch), and other sores of like appearance, are liable, on occasion, to take on the characters of puru sores. Leech-bites, although very common in jungle districts, do not receive much attention in this connection, but there is a belief among some Malays that the sores caused by contact with the fresh "getah," or live sap of a common fruit tree called in Malay pokoh machang (the horse mango, *Magnifera fœtida*), is a ready vehicle for inoculation by puru should there happen to be cases in the neighbourhood.

Sores on the lips and about the mouths of children may often be caused by eating the acrid fruit of this wild mango. The juice of the durian blossom (*Durio zibethinus*, L. Malvaceæ) is also blamed in the same way. These trees, however, are seldom avoided in consequence. Puru is well known to attack people both before and after they have suffered from small-pox. Small-pox is common in the uncivilised states, and educated Malays in the Federated Malay States often attribute the decline of puru (in Selangor, for example), as well as the apparent immunity of Europeans and their children, to the fact that, as a rule, all European residents and their children are more or less well vaccinated in childhood. Malay children, however, who have been well vaccinated readily contract puru, and it is more practical to account for the apparent immunity of Europeans and their children by explaining that they are not very much exposed to the contagion of puru.

It would be exceptional for European children to have many native playmates in places where puru was common. As a matter of fact, most Europeans, by reason of the refining influence of civilisation, are reluctant to come into personal contact with the loathsome-looking sores of puru. The advance of civilisation among the Malays in this respect, together with the influence of modern sanitation, should tend towards the check of the disease. In the civilised states of Selangor and Perak puru used to be far more common in the towns than it is at present.

Malays do not appear to associate the idea of flies or insects being possible agents in spreading puru, and although their expression, "bagi lalat chari puru" (as the fly seeks the sore), is used in conversation, it is applied more in the sense of the English saying, "Where the carcase is there will the eagles be gathered together." The common house-fly (*Musca domestica*) is not very prevalent.

Malays live rather poorly, the peasants mostly on boiled rice and dry salted fish, but diet does not appear to have much influence in the causation of puru. Native settlers, especially Chinese, favour a far more liberal diet.

In Kelantan, the practice of eating a home-made condiment of badly preserved sea-fish is very common. It is made by pounding two kinds of small fish (in Malay, bilis and kikih), salting them, and adding a little water. The young fish are chosen, and the raw preparation is kept for forty days, and when in a state of decomposition is ready to be eaten with rice. It is called "budu" and "peda" in Pahang. Dr. Hanitsch, the Curator of Raffles Museum, Singapore, has kindly identified these fishes for me. The larger of the two, ikan kikih, is *Equla edentula*, which is distributed in the Red Sea, Seas of India, Malay Archipelago and beyond. The smaller, ikan bilis (lit., ikan, a fish), is *Engraulis indicus*. It is very common about Singa-

pore, belonging to the family *Clupeidæ*, which comprises herrings and sardines.

Some Malays in Kelantan attribute the prevalence of puru in this state to the comparatively large amount of budu which is consumed by Kelantan Malays. The custom, however, seems to be peculiar to the eastern and northern states and to be in no way responsible for the origin of puru.

In Kelantan a very widespread and fatal disease occurs among fowls. It is characterised by an eruption about the beak and eyes, often leading to blindness. I have not, however, been able to trace any clinical resemblance between it and puru as it occurs in human beings.

The Clinical Characters of Puru.

Puru is universally recognised by Malays as being a specific disease. They have carefully observed the constant groupings of its symptoms and have given differential terms to its various manifestations. The most prominent of the well-marked clinical characters is the appearance of the eruption of the puru sores as it occurs in Malay children.

The disease attacks otherwise healthy and robust children, and observers with any experience of puru cannot fail at sight to recognise the eruption of puru sores in Malay children owing to its constant and uniform appearance. In the later stages of the disease it is not so easy to speak so definitely nor to recognise the sequence of the symptoms.

There is a stage of incubation, efflorescence, decline and sequel, but Malay children are seldom seen during the early stages of puru. In adults, again, the eruption of sores is more likely to be seen among foreign native settlers. Malays have mostly experienced it in childhood. The incubation period is therefore difficult to determine. It is given off-hand by most Malays as being twenty days. The attack is generally preceded by an ill-defined constitutional disturbance which causes some slight fever, as well as rheumatic-like pains in the bones, back and limbs. These symptoms are occasionally delayed or suppressed through chills, and it is said that the prodromal pain in the bones is then very pronounced and the backache equal in severity to the pains of small-pox. The joints in such cases are tender and swollen quite early in the disease.

The initial puru breaks out all over the body as a miliary papular eruption (" ketut " in Malay), and often in successive crops. It is attended with great itching, so much so as to give occasion for the Malay proverb, " Orang yang puru gatal tubohnya neschaya menggaru juga kerja-nya " (A man whose body is itching with puru will always be engaged in scratching it). I doubt, however, if the itching is sufficient to keep Malays from sleeping. Children often complain of feeling chilly at this early stage of the disease; they are feverish, peevish, and disinclined to bathe. The efflorescence of puru, known in Malay as the " bunga " (a blossom), develops gradually from the primary papular eruption. The " point d'appuie " is most often at some simple scratch or small sore from which springs what is known in Malay as the " puru ibu," or mother sore. This is formed by a combination of several papules and is generally the largest sore as well as the best developed and the most persistent. It is most often found below the waist, on the foot, leg, or thigh, but it may occur on the wrist or hand. This particular clump of papules may assume a horseshoe shape, or may develop into a large sore, as in fig. 1.

Malays always fancy the " puru ibu " to be the initial sore, and they often think it is a misfortune if it should disappear early in the disease. It is often the last sore to heal. Malays also think that it is impossible to arrest the development of the " puru ibu " and so prevent puru from spreading over the body and subsequently affecting the joints.

The " bunga puru," or efflorescence of the disease, originates from the papular eruption and seems to spring up like seed planted, as it were, beneath the skin and to grow up into a crop of tubercles which gradually bursts through the skin and expands into a number of discrete lesions, which ultimately become the typical clinical features of puru. Many of the original papules, on the other hand, involute and subside. There seems to be no reason (such as irritation from scratching, &c.) for some of them to develop into puru sores while others, and perhaps the majority of them, disappear. As they develop they are moist by reason of a glairy, thin, scanty, but rather sticky discharge, and on cutaneous surfaces they gradually dry up and generally form sores which are covered with a hard, tenacious, dirty, yellowish crust. Puru sores at this stage are those which are most commonly met with. Pus, unless formed by irritation, is not as a rule found under the crusts, and in four or five instances I have found the discharge to be either alkaline or neutral to litmus paper.

The sores are scattered over the face, neck, trunk, and extremities. They are more or less disproportionate and vary very much—from a grain of maize to a betel nut, for example—in point of size. They are often flattened out, but always seemed to be indolent and insensitive. By soaking of the crust of a small and rather old typical sore the reddish and roughly granular contour of the swelling may be exposed. It is not unlike a raspberry in appearance. Multiple and typical examples may be seen in the armpits and on the penis.

Irregular-shaped sores are very common at the angles of the mouth, at and about the nostrils, on the buttocks, and about the anus and genitals. When the eruption is well out the general health is practically unaffected, particularly when the sores have dried and scabbed over. They seldom ulcerate to any extent. I have never seen them transformed into " sloughs."

The disease does not attack the viscera, so far as can be judged without the aid of *post-mortem* examinations; the nervous system and the larynx appear to be exempt. There is certainly no specific affection of the eye in puru; deep lesions of the tongue do not occur, but the sores are said to attack the mucous membrane of the mouth. I think this, however, must be rare. The symptom is known as " guwan " or " serawan " in children. It has possibly been confounded with " thrush." The occurrence of an attack of puru for the first time in old age is said to be grave.

Puru sores heal very slowly on their own accord, and when they are at last beginning to decline they

shrink and gradually disappear, leaving either dark purplish transient strains or a few dark superficial scars.

The disease is of long standing; it frequently lasts for one or two years, but often for a much longer period. Sometimes the initial papular eruption becomes scurfy ("puru sekam"), and in other cases it may develop in places into a serpiginous eruption ("puru kretas"). When the eruption comes out slowly constitutional symptoms ("senggai puru") are complained of, such as malaise, simple periostitis of the long bones, and painful swelling of the wrist, fingers, and other joints. These symptoms are not at all uncommon in adults. During the decline of the disease, reminders in the shape of tiresome sores may crop up long after the original sores have ceased to recur. This is, I think, especially noticeable with sores of the foot, which are very common in adults who have suffered from puru in childhood. They generally occur on the sole and are very painful until they have burst through the epidermis. The pain is said to be much aggravated in the bare-footed native by contact with the dung of the buffalo and chicken. In Kelantan they are especially common during the durian (the thorny fruit) season in July and August, and for that reason, I believe, are called "puru durian." These foot sores are also seen in children.

A kind of xerodermia, or keratosis of the skin, as shown on the hands in fig. 2, also occurs on the foot, and is ascribed to puru. In appearance it is like dirty parchment paper, but the dry skin frequently cracks and causes painful fissures. This must not be confounded with the common affection of the feet, known locally as "burok chelapah" (lit., burok, rotten; chelapah, soiling by the tread). It is due to walking barefoot on gravel or sand.

Although puru as a disease is liable to be very persistent and recrudescent, Malays never acknowledge any lesions of deep nature, such as nodes, chronic dactylitis, chronic arthritis, and deep ulcers, as being sequels of puru. Lesions of the kind shown in fig. 24 and Plates XXXIX. and XCI. of the New Sydenham Society's Atlas [15] are very common among Malays. I do not think, however, that in the case of the Malay peninsula one is justified in attempting to fit these facts into a clinical description of puru. They appear to me to be manifestations of syphilis.

(*To be continued.*)

THE ANATOMY OF THE BITING FLIES OF THE GENERA *STOMOXYS* AND *GLOSSINA*.

By Lieut.-Colonel G. M. Giles, I.M.S. (Rtd.).

(*Continued from p.* 102.)

The distinguishing generic characteristic of *Stomoxys* is, however, the form of the proboscis, which, though presenting a strong general resemblance to that of *Glossina*, differs so markedly in outline that it can be recognised at a glance.

The organ is shaped like a radish, with a bold curve, convex on the dorsal aspect, and is slightly swollen at the tip. With the exception of the ends of the labella, which are clothed with long thin hairs, the surface is almost nude. It is connected with the lower part of the face of the insect by means of a soft membranous piece consisting of the combined bases of the labium and maxillæ, and bears on its dorsal aspect, close to the face, the short, single-jointed

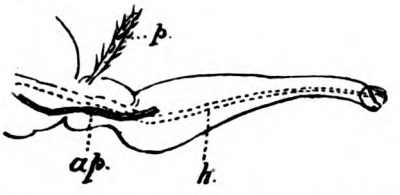

Fig. 13.—Profile outline of proboscis of Stomoxys. *p*, palp; *h*, dotted line indicating position of hypopharynx and labrum; *ap*, apodeme or sclerite which articulates with the fulcrum and serves as a jointed point of support to the proboscis. Semi-diagrammatic.

maxillary palps. This soft basal portion is about a quarter the length of the main radish-shaped part of the organ, and its length and flexibility permits of ample motion in flexion and extension, and to some extent also of protrusion and retraction, the necessary stability of the radish-like part being afforded by a pair of slender chitinous rods, the furca, which articulate with the fulcra, at their proximal ends, and distally, with the bases of the lancets.

Through the axis of this flexible basal portion runs a chitinous tube, continuous behind with the buccal cavity, and in front with the grove of the lancet, which in this insect consists of the labrum only.

Fig. 14.—Head of Stomoxys in profile.

The above rough sketch gives a fair idea of the organ in the position it is usually carried by the insect, but the basal portion is often flexed backwards almost against the base of the head, and on the other hand the trunk portion can be extended so as to almost touch the antennæ.

A glance at the profile outline below shows that it would be difficult to plan a sheath for the lancets less suited to act for itself as a piercing organ. The labella form an ostentatiously blunt extremity to the organ, and are furnished with delicate hairs and elaborate tactile organs, while the abrupt thickening of the basal four-fifths makes it clearly impossible that it should ever act as a rapid piercing organ, if, indeed, it could be in any way possible to employ it as such. No boring instrument that I know of, devised either by Nature or by man, has this form, and when, for want of a better

tool, one is driven to try to use a piece of steel of this shape as an awl, one at once finds how utterly unsuited it is for the purpose. Let any one who doubts this try to sew leather or canvas with an ordinary packer's needle, which is efficient for the workman's purpose, merely because the sacking he works with is of so open a texture as to be almost a net, and yet the tool is better shaped than the proboscis of Stomoxys, as would soon be seen if one tried to sew sacking with a needle so shapen. Those who have been driven by emergency to use an ordinary sewing needle for suturing the human skin will fully appreciate the force of these arguments, though a sewing needle has a far more delicate point than the proboscis of this fly, and the needle, for strict comparison, should have its point broken off. The labrum, on the other hand, which has a point fashioned exactly like that of the ordinary and very business-like hypodermic needle, is as admirably adapted for piercing as the labium is the reverse, as may be seen from the accompanying camera lucida outline of the two organs drawn from a fly in which the labrum happened to lie separate from the sheath.

FIG. 15.—Outline of head of Stomoxys seen from side and rather from above.

Let us now examine more closely the structure of this organ. The proboscis in the ordinary resting position of the parts as seen in the living insect shows nothing but the labium, or lower lip, the function of which, as already noted in a preliminary communication to this Journal, is, I maintain, simply that of a sheath to the true piercing apparatus. The main part of this consists of a radish-shaped mass, already sufficiently described, and this supports a pair of small lobular organs, the labella, which, apart from the relative proportions of the parts, resemble the larger expansions which are so familiar to us in the favourite popular microscopic object usually labelled as the "tongue of the blow-fly." These lobes are obliquely articulated with the slightly constricted trunk of the proboscis, and in the fresh state can be made to separate by pressing the proboscis down on an object slip or other resisting surface. When in this position, it is needless to say that the labella make the labium even more obviously impossible as a piercing organ than when folded together in their ordinary posture of rest.

If we now proceed to dissect the separated proboscis it will be found that it is not difficult to separate the black outer coating, except from the labella, and that when this is done, we are left with a delicate plate of chitin (sclerite) which forms a sort of median antero-posterior septum, and on either side a great mass of muscle which takes origin from the chitinous furca, which just reach up to the beginning of the thickest part or bulb of the proboscis, and is inserted into the anterior part of the median scleriti by tendinous fibres of varying length. Hence if the proboscis be detached by cutting it off immediately behind the bulb the muscular mass separates from the containing integuments with the greatest facility owing to its being left quite without hinder attachments. Behind, however, there is nothing to prevent the median sclerite from sliding back between the furca.

If we now examine a specimen from which the soft parts have been removed with caustic soda, it will be found that the outer skin, in spite of its blackness and deceptively solid appearance, is thin and flexible, and is, moreover, wrinkled transversely at fairly regular intervals. These transverse folds run almost transversely round the basal part of the proboscis, but towards its extremity, run rather forward on the ventral side to meet together in broad V's. These transverse lines give to the entire organ a close resemblance to a leech, which is much heightened by the remarkable similarity of general contour, and it is impossible to interpret them in any other way than that they are the outcome of habitual infolding which, exactly as in the leech, permits of the whole structure being shortened.

If we now examine a transverse section of the organ it will be found that it consists of a solid conical mass, the anterior side of which is grooved with a narrow rabbet, the depth of which, however, is not more than

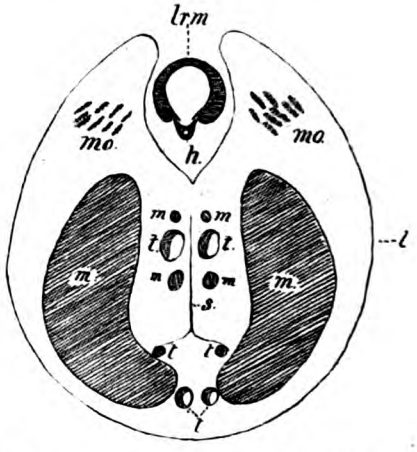

FIG. 16.—Transverse section of proboscis of Stomoxys at about mid-length. *h*, Hypopharynx; *l*, labium; *lrm*, labrum; *m*, muscle; *s*, median sclerite; *t*, tracheæ. Camera lucida, semi-diagrammatic.

one-third of the thickness of the cone. Dividing it into two lateral halves is the median sclerite which is stouter on its ventral than on its dorsal edge, and lies immediately under the skin of the groove dorsally, while the stout ventral margin has attached to it two delicate septa which run off on either side to the great muscular masses and serve to separate the ventral median from the two great lateral air sacs. The entire width of this sclerite is little more than one-third that of the diameter of the cone, and as its thin dorsal edge is close under the rabbet, while the

ventral edge is almost a third of the diameter of the organ from the ventral integuments and separated from them by the great ventral median air chamber. Lying on either side of the axis of the cone are two great tracheæ which break up in front into branches which appear to open into the two antero-lateral air sacs. Behind and in front of each trachea are extremely slender muscles, the hinder rather the thicker, the function of which I am unable to make out, but conjecture that they are in some way concerned in keeping the crease between the labellæ from outfolding under the air pressure of the pneumatic sacs. In the dorsal portion of the section within the alæ forming the sides of the rabbet are seen a number of obliquely divided muscular films. There are two sets of these which serve respectively to separate and to bring together the labellæ; so with the difference that the prehensile lobes of the labella are lateral and symmetrical instead of different and antero-posterior, the whole proboscis presents some resemblance to that of an elephant, though the labella are, of course, relatively far larger. What purpose a pair of soft, hinged flaps can serve, when considered as the point of an awl, is difficult to understand, and it is for those who assert that the function of this elaborate mechanism is simply to pierce the skin, as a bradawl is driven into a plank, to show what may be the object of all this complication, and what may be the function of the various muscles and other parts concerned.

A minute description of even the external anatomy of the labella would alone occupy a lengthy paper, for

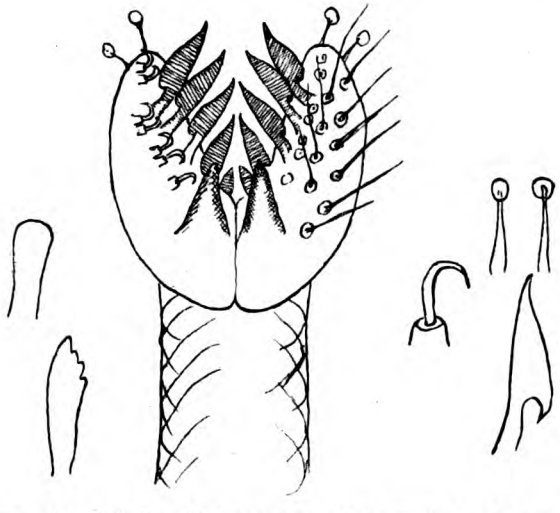

FIG. 17.—Labella of Stomoxys seen from ventral side to show the rank of large teeth. To avoid confusion, the complicated ranks of plates behind them are not represented, and only a couple on each side of the pellate hairs of which about a score are scattered over the end and sides of each labellum. On the left side is shown the rank of grapnel hooks, and on the right the position of these is only indicated by small circles so as to show better the double rank of long bristles.

it is provided with so great a variety of hairs, plates and sense organs that it is extremely difficult to condense an adequate account of it into moderate limits. Internally it is simple enough, the entire space, with the exception of some muscular fibres which are inserted into the bases of some of the larger plates or teeth, being occupied by a large air sac continuous with those of the main trunk of the proboscis, so that the point of this reputed borer is formed by an air cushion.

Viewed ventrally, with the labella slightly separated, it will be seen that the most prominent structures are a row of strong leaf-shaped blades or teeth which project inwards and forwards towards each other, so that in the natural position of rest they are folded together and cannot engage the skin of the blood-yielding animal except when the labella are spread out to full expansion. They are four or five in number on either side (I am not sure of the hindmost, which may belong to another rank of plates), and are the only at all powerful teeth that are to be found, though it is difficult to see how they can effect a sufficiently large wound to admit of the rest of the structure following them. On the other hand, it is easy to see that they can form efficient holdfasts if the labella are pinched together after they have entered the skin when they have been applied to it with labella expanded.

Outside these is a row of very obvious grapnel hooks. These are arranged in pairs, with the exception of the hindmost, which is single, each pair being opposite an interspace between the leaf-shaped blades. Finally, outermost of all, is a double row of rather long, stiff bristles. Quite behind, on either side of the fold between the labella, is a large papilla. The whole of the tips and outsides of the distal third of the labella is sprinkled with very peculiar pellate hairs of extremely delicate structure. There are a score or more of these on each, but a couple only have been drawn to show their relative size, as to do more would needlessly confuse the figure. Their function is probably sensory, and it is conceivable that they may be gustatory organs, as the membrane of the little shield at the end is excessively delicate. From their form and delicacy it is obvious that they would never outlast the labella being once forced into the skin.

To obtain an idea of the complex system of plates and structures behind these it is necessary to make a dissection so as to clear away one

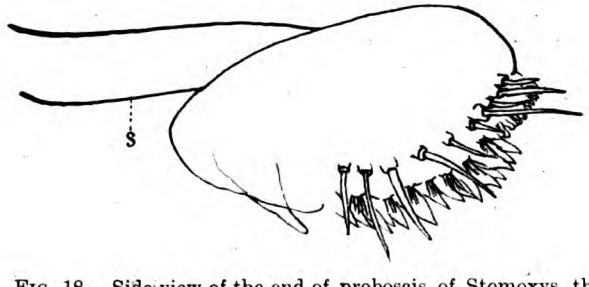

FIG. 18.—Side view of the end of proboscis of Stomoxys, the integument and muscles being removed to show the median sclerite.

labellum, and in doing so, by clearing away the integuments of the supporting trunk, it is easy to establish that the true support of the labella is the median sclerite (*S*) already described. When this

has been done it will be seen that inside the large leaf-shaped blades are two or more ranks of extremely delicate lancet-shaped structures. Next to these a row of tufts of short dense bristles, and inmost a rank of stout bristles. On the most anterior part is a dense mass of minute hooks. Personally, I regard these curious structures as having the function of sufficiently abrading the surface to admit of the character being tested by taste, but there is nothing whatever in their size and form, or in the fact of their presence, to suggest that they are in any way concerned in any deep piercing of the skin of the animal that yields blood to the fly, for "teeth" of this sort are to be found on the labella of all Muscidæ, such as the common house-fly, and which certainly are quite incapable of doing anything more serious than of licking the surfaces of what they feed upon.

I cannot give the exact reference, but if any one cares to look up the files of *Science Gossip* of the early eighties, he will find a series of very interesting papers on these teeth of flies, which are illustrated by some very beautiful coloured plates, and will find that many of the most harmless flies have much more formidable teeth than those with which *Stomoxys* is provided.

RHINO-PHARYNGITIS MUTILANS.

By C. W. Branch, M.B., C.M.Edin.
Medical Officer, Colonial Hospital, St. Vincent, B.W.I.

Under this title, in the Journal of Tropical Medicine for February 15th, 1906, Dr. Leys describes a condition which he suggests is a distinct disease. As one with some experience of practice in the Tropics and of this particular condition, I wish to raise a protest against this manufacture of new diseases out of the manifestations of syphilis.

A mere pathological entity should not be put forward as a disease *sui generis*. By this process we have had several diseases created out of tuberculosis. Syphilis of the nerve system has provided locomotor ataxia, general paralysis, &c. But perhaps the most fertile field for the discovery of new tropical diseases is syphilis of the skin.

Considering the incalculable importance to the human race of the recognition of syphilis, and the difficulty as yet of confirming diagnosis by any certain test, it is most inadvisable to claim independence for any condition, which may reasonably be attributed to syphilis, until its etiological individuality can be established.

Far better is it to treat everything as syphilis than to miss the diagnosis of half the cases of syphilis. In the Tropics, at least, this is true, where perhaps two-thirds of the sickness is syphilis.

This destructive rhino-pharyngitis is extremely common in some parts of the West Indies. Those of us who do not attribute it to syphilis call it, with Dr. Rat, a tertiary of yaws.

Of all works on yaws, that of Dr. Rat is perhaps the best. He is a careful and conscientious observer, but, as can be seen by his laborious compilation of previous writings, he is limited by his reverence for tradition and authority. This, however, could not detract from the accuracy of his descriptions, and I believe any one who reads his report with an open mind must see that, after all, yaws is only syphilis, as Jonathan Hutchinson says in his preface to Rat's report.

We are yet at the threshold of the arcana of syphilis, though the disease would seem to be as old as Pithecanthropus, and is clearly referred to in the Chaldean epic of Izdubar.

To understand this protean disease we must realise that various factors intervene to determine its manifestations. We can appreciate some of these. The races or individuals who tax their nerve systems suffer from nerve syphilis, which is comparatively rare among negroes.

The negro, with his highly specialised and active skin, displays an exuberance of eruptions rarely seen in Europe. The labourer exposed to injuries develops grave bone lesions. The women in St. Kitts, who habitually gratify the desire of sailors for pedicatio mulierum, get stricture of the rectum.

Some of the determining factors we have yet no knowledge of, others we can now guess at.

In yaws Castellani found a spirochæte morphologically identical with *Spirochæta pallida* and one or more of the *refringens* type. If we assume for the present that *S. pallida* has an etiological significance in syphilis, then the other spirochætes, or perhaps bacteria, may be the determining factors explaining the form of the yaws eruption.

I find in dirty sores, which have no apparent relationship to syphilis or yaws, spirochætes of one or more types which are identical with those I find associated with *pallida* in yaws. I think I can recognise sores in which these spirochætes will be found.

Some cases of another kind of sore have been observed associated with great œdema, but not inflammation of the legs. These are considered by myself and another man who has seen them with me to be due to tertiary syphilis. But they showed a marked identity and distinctness of features, and one finds another spirochæte in such swarms that the secretion consists almost entirely of the organisms, with very few pus cells.

Until the relationships of *S. pallida* and *Cytorrhyctes luis* to each other and to syphilis are worked out, or until some other certain test of syphilis is established, we have no right to foist a new disease on an already overburdened list. It must be possible, first, to exclude syphilis by the absence of some essential element.

Dr. Leys tritely calls attention to the disproportion in numbers of his cases and those of Dr. Rat in Dominica to the populations, and compares the frequency of syphilis of the palate and pharynx in a large European community. I noticed in a hospital report for 1902 (Colonial Reprints, Medical Reports, 1904), that destructive rhino-pharyngitis was exceedingly common on the leeward side of St. Vincent, while on the windward side destruction of the face took its place. Syphilis is equally prevalent on both sides of the island, but the land conditions are very different. The leeward side consists of deep ravines with numerous streams; there is dense tropical growth and combined heat and moisture.

These same conditions obtain in Dominica, in parts of St. Lucia, in Grenada, but not in Nevis nor Anguilla, and hardly at all in St. Kitts. Since he left Dominica Dr. Rat has been stationed in St. Kitts and Anguilla, and is now in Nevis. He has not observed the destructive rhino-pharyngitis in these places.

I have no doubt that Guam provides the conditions I have attributed to the leeward of St. Vincent, and shall be interested to hear from Dr. Leys, whose address is, necessarily, a changing one.

Syphillis and yaws are excessively prevalent in all West Indian colonies. Syphilis more so where yaws is not much accredited, as in St. Kitts and St. Vincent yaws, that is, the frambœsial eruption, is certainly, I admit, more prevalent under the same conditions referred to as favourable to rhino-pharyngitis.

Since reading Dr. Leys' paper I took the first opportunity of examining smears from a case of "leeward sore throat," as I have been in the habit of calling this condition. There was present in small numbers a spirochæte, other than *pallida*, in a scraping from the active edge of the ulcer. Pus from the surface did not show any spirochætes.

I shall pursue this enquiry as opportunities present. My suggestion is that it may be varieties of spirochætes which determine the form of the manifestation of syphilis in the case of yaws which is a secondary, and in rhino-pharyngitis mutilans and my "œdematous sore foot," which are tertiaries.

"Annales de l'Institut Pasteur," Paris, vol. xx., No. 1.

YELLOW FEVER AND MOSQUITOES.

Marcheoux and Simond, in their second report of the French Yellow Fever Commission in Brazil, state that the *Stegomyia fasciata* is the only mosquito known which does not die after depositing its first batch of eggs. The female may lay several batches of eggs. Infection of the mosquito by heredity, although possible, is not general. *Stegomyia* do not feed on the black vomit, stools, or blood from the hæmorrhages occurring in yellow fever patients, unless compelled to by want of other food. The larvæ of *Stegomyia* developing in water in which dead infected mosquitoes have been thrown do not acquire the power of infecting man. In only one case was hereditary transmission experimentally proved, and the resulting infection of man was very mild. The *Stegomyia fasciata* mosquito, kept at a temperature of 68° F., loses power of infecting. The virus of yellow fever has been artifically transmitted from one mosquito to another in the laboratory, but successive passages proved negative. During the incubation stage of yellow fever, mosquitos cannot become infected.

"Bulletin et Memoire de la Société Méllicate der Hôpitaux de Paris," February 1, 1906.

QUININE FORMATE.

Lemoine, G. H., advocates in the early stage of malarial attacks an hypodermic injection of quinine formate, 3 grs. in 1 oz. of water.

"L'Echo Médical du Nord," February 26, 1905.

TREATMENT OF ORIENTAL SORE.

Malméjac, F. As the result of experience at Biskra, the author finds the best local treatment is boiled distilled water at a temperature of 60° C. (140° F.). When crusts are present a stream of water is allowed to flow on these, especially into the edges and cracks. A dry antiseptic dressing is then applied. The treatment is repeated twice a day for a week, the crusts usually separate in two or three days; at the end of a week only one dressing a day is required.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

MAY 15, 1906.

A LESSON IN PRESERVATION OF HEALTH IN THE TROPICS.

REPORT OF THE PRESIDENT OF THE SAPELE SANITARY BOARD, DECEMBER 31, 1905.

SIR RALPH MOORE, when authorising the arrangements laid before him for sanitary work here, gave it as his opinion that three years should show whether the scheme to be applied was of value or not. These three years have now been completed, and I am glad to say that the experiments of making a Local Sanitary Board has proved a success, and further, to tell you that as a consequence a Local Board is about to be made at the town of Ko Ko further down this river, where Europeans are now also residing.

The supreme obstacle to systematic and continuous work in tropical West Africa is the rapid changing that sometimes takes place in the *personnel* which has to carry out the work, and it is for this reason that a Board composed of traders and officials was constituted, because it was seen that a Board would not "go away," and further, that it would have a continuous knowledge of the policy to be pursued. You will appreciate how great the change amongst individuals sometimes is, when I tell you that during the three years the Board has existed there have been five, I might almost say six, different administrators holding the office of High Commissioner, four different officers have acted as Divisional Commissioner, four others have acted as District Commissioner of Sapele, four others as Assistant District Commissioner, and, moreover, there have been three District Medical Officers here; finally,

with the exception of the doctor who started the whole scheme and has recently returned here, there is not a single member of the present Board who was also a member of the Board when it started.

The triumph of the Board is that not only has it lived through all these changes and done good work, but also that the local changes, with possibly one exception, were not due to ill-health.

The Board acts in four ways: Firstly, it acts by actually carrying out sanitary work, removing vegetation, surface water, &c.; secondly, it acts as an object-lesson, inspiring bush clearing, &c., even where a sanitary board does not exist; thirdly, it acts by interesting Europeans in sanitation, and as a corollary in quinine-taking as a preventive of malaria; fourthly, in proving the value of a sanitary board, it supports the arrangements for creating one at Ko Ko.

During the time the Board has been at work it has succeeded in dealing with almost the whole area of the reservation; and although parts of this area are not finally finished, yet a considerable portion around the European dwellings has been completed, and the work done will in future require only to be kept up.

The Board has tried many ways of employing labour; local boys, boys from the Benin country and the Ejor country have been tried, also prison labour, and the conclusion that has been come to is that no matter what labour is employed, it is best to give out the work as piecework, either to individuals or native contractors.

I have here certain figures gathered from the records of the Sapele District Medical Officers, and from them it will be seen that the healthiest time of the year here at Sapele used to be, and still is, the rainy season. This is the period of lowest maximum temperature. The figures, expressed graphically, show that the curve of the sick list falls as the maximum temperature falls and the rain curve rises. The sick list curve is now altogether so near zero that it is difficult to appreciate its undulations, but June, which is always one of the heavy rain months, this year had no European inhabitant sick during its entire length.

We are fortunate in having no death among the *bona fide* European inhabitants of Sapele for more than three years, this, though a thing to be thankful for, must not be considered too much, for that death will occur both at home and abroad we all know only too well. In the Blue Book for 1904, relatively a large number of deaths are shown under the name of Sapele, but these deaths occurred in people living in outlying parts of the district, and not to inhabitants of the reservation.

What these vital statistics mean, put commercially, is this, that for a cost of 9s. per month for each European of Sapele Reservation for the year 1905, his chances of being sick have been reduced from five and four-fifths times each year to one and two-fifths each year.

A new firm has commenced business on part of the land cleared and reclaimed by the Board, and I have reason to believe that the rent paid by it will be given to the Board to be expended in still further work. There is a lot still to be done; keeping down the vegetation is itself a labour like rolling a big stone up an endless hill.

During the incoming year, however, the question of disposal of refuse or water supply might, with advantage, be considered. In any event, I am confidently hoping the future members of the Board will be keen to maintain the record, namely, that in spite of an increasing European population the amount of sickness decreases, and that they will cause the Board to remain in the sound financial condition it has always enjoyed.

FRANZ STAHL, *President.*

"HORSE-FLIES (TABANIDÆ) AND DISEASE."

To the Editor of the JOURNAL OF TROPICAL MEDICINE.

SIR,—In my article under the above heading in your issue for April 2nd last, I unfortunately omitted to mention that in Algeria it has been shown by Drs. Edmond and Étienne Sergent, by means of experiments upon laboratory animals, that *Tabanus (Atylotus) nemoralis*, Mg., and *T. (Atylotus) tomentosus*, Macq., are capable of transmitting the trypanosome of the disease of dromedaries, called *Debab*, which occurs from Morocco to Syria, and more than decimates the Algerian camels. In most of the experiments transmission was direct, but in one case, in which six or eight specimens of *Tabanus tomentosus* were used, an interval of twenty-two hours had elapsed since the flies had

bitten an infected rat. Actual experiments upon camels do not appear to have been made, but the natives of North Africa always assert that the disease is transmitted by *Tabanidæ*, and camel-drivers declare that the two species mentioned above, which apparently are far more common in Algeria than any others, are especially dangerous to camels. The disease, which is almost invariably fatal, commits great havoc among animals that have passed the summer in a locality where horse-flies are numerous, but among others that have spent the time in a place where *Tabanidæ* are almost absent its incidence is slight *C.f.*, "El-Dehab Trypanosomiase des dromadaires de l'Afrique du Nord," by Drs. Edmond and Étienne Sergent (*Annales de l'Institut Pasteur*, T. xix., January, 1905, pp. 17-48). My thanks are due to Dr. Edmond Sergent for his kindness in drawing my attention to the very interesting and important paper in question.

I am, &c.,

ERNEST E. AUSTEN.

British Museum (Natural History),
Cromwell Road, London, S.W.,
April 28th, 1906.

Abstract.

CARRION'S DISEASE: VERRUGA PERUANA AND ITS BACTERIOLOGY. By Dr. M. O. Tamayo (*La Cronica Médica*, November 30 and December 15, 1905.) Translated by M. D. Eder.

Dr. Barton, in 1899, isolated a bacillus from the spleen in several cases of pernicious fever in Carrion's disease. He described the bacillus, pointed out its differences from the *B. coli*, and concluded that it was the specific causal agent of verruga peruana.

We have examined all cases of this disease that we have been able to find in the hospitals of Lima during the last few years; they number thirty in all.

Our studies confirm Dr. Barton's researches, in so far as that the organism he described is indeed frequently present in such cases. Clinically, the thirty cases may be divided into two groups:—

(1) Those where fever was the main clinical symptom. This comprises most cases.

In twenty of these cases bacteria were found in the blood during pyrexia, which, by their morphological and cultural characteristics, belong to the paratyphoid group.

In periods of apyrexia in most cases the blood did not contain the organisms (see Case 10).

(2) Those without fever.

In these cases no bacilli were found. Our cultures, whether made from patient's blood, from the juice of the warts, or fragments of these growths, remained sterile.

The bacteriological work consisted in:—

(*a*) Microscopic examination of the blood and fluids of patients.

(*b*) Cultures from the blood on different media (we used a sterile Pravaz syringe for withdrawing blood from the veins, the skin being previously carefully disinfected).

(*c*) Inoculation on various animals—guinea-pigs, rabbits, Chinese dogs (*Canis caribeus*), three horses, and one monkey.

(*d*) In fatal cases we made cultures from the blood of the heart, spleen, liver, pulmonary veins, and from portions of bone marrow.

Pure cultures are easily obtained from the blood of febrile patients. The bacillus grows rapidly on peptonised broth, agar, gelatine, &c., at 37°. The blood does not arrest the growth of the organisms (Eberth's bacillus). No bacillus was found in the blood under the following circumstances:—

(i.) In the apyrexial variety, where other symptoms were prominent, *e.g.*, copious eruptions, progressive anæmia, arthralgias. There was no question here of the fever being latent.

(ii.) In slightly febrile cases.

(iii.) Transitory rises of temperature in cases that were running a typically afebrile course.

Inoculation experiments with pure cultures gave the following results:—

(1) A few drops[1] inoculated into the subcutaneous tissue of rabbits weighing 1,500 to 2,000 grammes frequently killed them, the animals dying with all the symptoms of acute septicæmia.

(2) Intraperitoneal inoculations usually caused death with *post-mortem* signs of acute peritonitis.

(3) In some cases intravenous injections did not cause the death of the rabbits. After a few days of fever and signs of septicæmia the animal recovered; there was at no time any eruption. When the animals were killed some months afterwards, no eruption, external or internal, was found, nor did we find any pathological condition, either recent or old.

Guinea-pigs are also very susceptible to inoculations. Intravenous inoculations produce a rapidly fatal septicæmia.

Dogs are more resistant. Intravenous injection of small quantities of a virulent culture give rise to fever which disappears in a few days. Repeated inoculations can be made until the animal becomes immune. The serum is then agglutinative for the same bacillus. Careful observation during many weeks showed the animals to be perfectly healthy.

Horses.—Injections of high potency and virulence were made into the jugular veins of three horses. Two recovered completely in a few days after having had some signs of a slight septicæmia. No granulomata or other effects appeared. The third animal died of acute septicæmia; it had received a large dose of a hypervirulent culture.

Small Monkey (*Ateles ater*).—Repeated inoculations with the blood withdrawn from the verrugæ, and with cultures of Barton's bacillus, gave no results. After a few days of slight septicæmic trouble he recovered perfectly, and is still in the Institute in complete health. His serum readily agglutinates the bacteria taken from the verrugæ.

To this experimental work we must add a few remarks on the clinical aspect of the febrile cases which is so very similar to that of typhoid fever. Note the general apathy, the dry tongue with its light band of fur, the tenderness over the epigastric and the hypochondriac regions. Diarrhœa is a fairly constant feature, and resembles in every particular that in enteric. The temperature chart is characteristic of enteric; there is at first a gradual daily rise; then a

25	None	Nodular ..	..	,, ..	,, ..	Negative.	
26	,, ...	,, ..	..	,, ..	,, ..	Pains in joints.	

(a) Thousands per cubic millimetre.

period of continued fever; finally, as convalescence ensues, the fever, synchronous with the attenuation of all the other symptoms, becomes remittent. The average duration of the fever is twenty-five to thirty days (Odriozola, " La Maladie de Carrion ").

It must be noted that there is no connection between the fever and the order of the appearance of the granulomata. Sometimes the fever ends just when the verruga appears; sometimes the reverse holds good—the verruga disappears and fever commences.

To sum up our results :—

(1) Barton's paratyphoid bacillus is found only in cases of pernicious fever of Carrion's disease.

(2) Inoculations do not give rise to verrugæ, but to a typhoid septicæmic state.

(3) Carrion's pernicious fever is a typhoid or paratyphoid disease, attacking the patients suffering from verruga.

(4) Barton's bacillus is not the pathogenic agent of verruga peruana.

(5) Barton's bacillus gives rise to a secondary infection occurring during an attack of verruga, which attack predisposes to the infection. This secondary affection has all the clinical characteristics of enteric fever.

Review.

THE MANAGEMENT OF A PLAGUE EPIDEMIC. By E. F. Gordon Tucker. Calcutta: Thacker, Spink and Co., Government Place. 28 pp. Illustrated. Price 1·8 rupees.

The substance of this concise book appeared in *Indian Public Health*. The object of the writer is to present in a readily followed statement the steps to be taken by a medical officer placed in charge of a town or district stricken with an epidemic of plague. The subject is dealt with under the following headings: (1) The Termination of the Period of Quiescence; (2) The Arrival of the Primary Infecting Agent; (3) The Stage of Sporadic Atypical Cases; (4) The Stage of Local Place Infection; (5) The Early Epidemic Stage; (6) The Fastigial Stage of the Epidemic; (7) The Stage of Decline; (8) The Stage of Residual Infection; (9) The Commencement of the Period of Quiescence and a Temporary State of Local Immunity. An excellent book, that will prove a great help to any medical man placed in charge of an outbreak of plague in any part of the world.

Drugs and Remedies.

TREATMENT OF BLACKWATER FEVER.—The Bipalatinoid, prepared by Oppenheimer, Son and Co., 179, Queen Victoria Street, London, E.C., for use in the treatment of blackwater fever, continues to give satisfactory results.

Full particulars have been reported upon no fewer than twenty-one consecutive cases of recovery, without a single death, and without sequelæ or complications of any form of urinary suppression. This experience is encouraging and unique, and we hope to hear of further cases in which this bipalatinoid has been used. It will be remembered that it was the Principal Medical Officer of British Central Africa who suggested the treatment to Messrs. Oppenheimer in the first instance.

"TABLOID": SODIUM CITRATE.—Messrs. Burroughs Wellcome and Co. have prepared a sodium citrate "Tabloid," grs. 2 (0·13 gm.), for use in cases in which either the mother's milk or cow's milk does not suit the infant.

The digestibility of cow's milk is greatly assisted by the addition of sodium citrate. The explanation of the action which is commonly given, is that the acid caseinogen and the calcium salts of milk in presence of the gastric juice form a thick casein clot. If sodium citrate be added to the milk, it combines with the caseinogen to form a sodium compound less dense and more absorbable than the calcium caseinogen compound in the normal milk clot. The calcium salts in the milk unite with the citric acid of the sodium citrate and the resultant calcium citrate is diluted by the stomach contents and absorbed. Thus the introduction of sodium citrate increases the digestibility of cow's milk in a remarkable manner, allows the absorption of the calcium salts, and greatly enhances the food value of the milk.

Notes and News.

W. J. R. SIMPSON, M.D., F.R.C.P., D.P.H., Professor of Hygiene, King's College, London, and Lecturer in Tropical Hygiene at the London School of Tropical Medicine, has sailed for Singapore to serve on a Commission to enquire into and report upon the sanitary condition of Singapore. The appointment was made by the Colonial Office acting on behalf of the Government of the Straits Settlements. Professor Simpson's excellent work, whilst engaged on similar commissions in South Africa and Hong Kong, is fresh in our memories, and we anticipate equally brilliant results from the present Commission.

Surgeon-General James Pattison Walker, who died recently, at the age of 86, joined the Medical Service of the East India Company in 1845. He served with distinction during the Mutiny, and amongst other important positions he occupied the Chair of Hygiene in the Calcutta School of Medicine.

Whilst H.M.S. *Black Prince* was on view to the public, the ship was visited by 21,000 persons. No less than £1,100 was received for the benefit of the Seamen's Hospital Society and the Poplar and West Ham Hospitals.

Surgeon-General Spencer, I.M.S. (retired) has been appointed Honorary Surgeon to the King.

To remove rust from instruments, according to the *Pharmaceutische Zentralblatt*, rusty surgical instruments are (1) placed for twelve hours in saturated solution of stannous chloride; (2) rinsed in water; (3) laid in a hot solution of soda soap; (4) dried; (5) or rubbed with absolute alcohol and (6) prepared chalk. Another method is to lay the instruments in kerosene. As a preservation against rust, paraffin oil may be applied as follows: The instruments, after being dried and warmed, are laid in a solution of 1 part paraffin and 200 parts benzine. Subsequently the benzine is allowed to evaporate before the instruments are laid aside.

The British Association meet at York on August 1st, 1906.

Association of Medical Officers of Missionary Societies.

The above Association was formed in March, 1904, on the initiative of Mr. W. McAdam Eccles, Dr. C. F. Harford, and Dr. J. N. Kelynack, and now includes, as members, medical representatives of practically all the foreign Missionary Societies.

The object of the Association is the discussion of subjects relating to the selection of missionaries as regards their physique and to all matters concerning the preservation of their health abroad.

Meetings take place quarterly at the various members' houses, and amongst others the following have opened discussions: Sir Patrick Manson, Dr. S. H. Habershon, Colonel T. H. Hendley, I.M.S., Dr. C. F. Harford, Mrs. Scharlieb, M.D., and Wm. McAdam Eccles, M.S., F.R.C.S.

Livingstone College.

On Thursday, May 31st, Livingstone College, Leyton, E., celebrates its Commemoration Day. The programme of proceedings is as follows:—

The chair will be taken at 3.30 by J. A. Simon, Esq., M.P. for the Walthamstow Division of Essex, unless prevented by his official duties.

An address will be given by James Cantlie, Esq., F.R.C.S., and by the Rev. J. E. Watts-Ditchfield, Vicar of St. James-the-Less, Bethnal Green.

A short statement as to the progress of the College will be made by the Principal, Dr. Harford.

Personal Notes.

Indian Medical Service.

India Office: Arrivals of Indian Medical Officers in London.—Lieutenant-Colonel P. D. Pank, Lieutenant-Colonel J. Sykes, Lieutenant-Colonel A. C. Younan, Captain W. H. Kenrick, Captain A. T. Pridham.

Extensions of Leave.—Lieutenant-Colonel A. V. Anderson, 6 m., Med. Cert.; Major A. R. P. Russell, 4 m., Med. Cert.; Captain L. Hirsch, 5 m., Med. Cert.; Captain R. D. Willcocks, 4 m., Med. Cert.

Permitted to Return to Duty.—Lieutenant-Colonel H. Armstrong.

Postings.

Dr. H. A. Macleod to Civil Surgeon, Saharanpur.

Major G. Y. C. Hunter officiates as Superintendent, Central Jail, and Civil Surgeon, Montgomery.

Captain C. J. Robertson Milne, Superintendent Central Lunatic Asylum, Lahore, in addition to his other duties.

Captain L. B. Scott, services lent to Government of Assam.

Captain N. S. Wells, services lent to Jail Department, Bengal.

Colonel A. M. Crofts, at disposal of Home Department.

Captain H. Ainsworth to Plague Duty, Lahore.

Major G. B. Irvine, Civil Surgeon, Jhelum.

Captain G. E. Charles officiates, Prof. Anatomy, Lahore.

Leave.

Major R. J. Marks, privilege leave, 2 m. 24 d.

Lieutenant-Colonel W. Coates, Med. Cert. and privilege, 7 m.

Major A. H. Nott, furlough and privilege leave, 17 m.

Major R. H. Maddox, combined leave, 18 m.

Domestic.

Births.

Oxley.— At Seoul, C.P., on April 5th, the wife of Captain J. C. S. Oxley, of a son.

Colonial Service.

J. B. Addison, M.R.C.S., L.R.C.P., is acting as Chief Medical Officer of the Seychelles.

*Dr. E. W. Blyden will terminate his five years' engagement with the Government of Sierra Leone on July 1st, 1906.

*Dr. J. D. Bolton, of Mauritius, has been appointed Government Medical Officer of the Dependency of Rodrigues.

R. Denman, M.R.C.S., L.S.A., D.P.H., Chief Medical Officer, Seychelles, is on leave.

A. Nicolle de Gruchy, M.B., C.M.Edin., Assistant Medical Officer, Seychelles, has been transferred to Southern Nigeria as Medical Officer.

G. F. Leicester, M.B., C.M.Edin., Assistant at the Institute for Medical Research, Selangor, Federated Malay States, is at present acting as District Surgeon in Selangor.

*Dr. A. J. McClosky, District Surgeon, Selangor, Federated Malay States, is on leave.

* Name not entered in the "Medical Directory" for 1906.

[Reference is made to the fact that the name is not entered in the "Practitioners Resident Abroad" list in the hope that all medical men abroad may see to it that their names are duly entered in this list.—Ed., *J.T.M.*].

Colonial Economic Notes.

Antigua.—The area of the cultivation of cotton was considerably increased during 1905. Owing to deficient rainfall both the cotton and sugar crops suffered.

Barbados.—Cotton cultivation is extending. Banana growing has received a check, as no profits are being obtained; regular mails and proper cool storage in all ships can alone restore the banana industry.

British Guiana.—It is proposed to appoint a Royal Commission to enquire into the condition of the Colony generally.

Montserrat has had a record cotton crop.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Nature," December 25, 1905.

THE PULSE OF THE ATMOSPHERIC CIRCULATION.

Shaw, Dr. Few of those whose lot is cast in the regions south of the Equator which are swept by the "Trades" have any idea that there can be any connection between the force of the wind current and the weather at home in England. And yet the above very interesting and suggestive paper advances strong reasons for believing that such is the case. Dr. Shaw himself regards his hypothesis as "too speculative for an official report," but "too suggestive to be altogether ignored," and the gist of the thesis is that strong southern trade winds are associated with wet weather in England and the neighbouring parts of the world.

This conclusion is based on the analysis of several years of anemometer records from the Island of St. Helena—and the curves plotted from these data correspond so closely with those of English rainfall that one can scarcely fail to agree with Dr. Shaw in the conclusion that the "connection can hardly be pure coincidence." The seasonal curves of the two sets of data correspond very closely, the minima of both falling in April, though the principal maximum of English rainfall, which occurs in October, lags a little behind that of the force of the trade wind which is found in September. What is even more remarkable is that the otherwise bold curve is in both cases broken by a second small rise in April. It is also undoubtedly the case that years of weak trade winds at St. Helena are associated with drought in England.

More than this, however, cannot be affirmed, as the proverbial fickleness of English weather makes the comparison disappointing when followed up in detail; so that, undoubtedly, other and disturbing factors are at work, and, as Dr. Shaw points out, "the transformation of energy in rainfall is on a vastly greater scale than that displayed by the trade winds." In any case, the observation seems promising, and emphasises the urgency of greater attention being devoted to colonial meteorology.

"Geographical Journal," February, 1906, p. 182.

CLIMATIC FEATURES OF THE PLEISTOCENE ICE AGE.

Albrecht, Peuck, Prof., bases his treatment of the subject on physio-geographical research, considering that attention has hitherto been too exclusively devoted to theoretical astronomical speculations, and to supposed alterations in the earth's axis of rotation. He shows that the snow-line "arches" across continents being higher inland than on their shores, the present level for Europe being almost 7,000 feet for littoral and 9,000 feet for inland localities. Now, in the Ice Age, what is now central Europe was near the sea, and at that time the snow-line for littoral regions was no more than 3,000 feet or less. The diminution of mean annual temperature required to produce such an effect need not, however, have been at all as great as one might imagine, "we are entitled to assume that a rather slight decrease of, say, 2° to 3° C., if connected with a diminution of the summer temperature will cause an ice age. Such a decrease will cause also changes in the amount and distribution of precipitation and the glaciations themselves will influence climatic conditions by altering the distribution of air pressure and the arrangement of the isothermic lines." The lowering of temperature was world-wide, being found as markedly in New Zealand as in Europe; and in latitudes too low for glaciation to result, a rainy period was substituted. In addition to the two great glaciations that occurred in the Permian and Pleistocene periods respectively, there have been minor variations of mean temperature, which have merely resulted in extension and contraction of existing glaciers in temperate regions; and of corresponding epochs of moisture and of desiccation in the warmer parts of the globe. At present the glaciers are contracting and the desiccation of the interior of the continents is in progress, but probably in course of time the opposite process will be substituted, as it appears that four hundred years ago the limits of the glaciers were very much as they now are, though there has been an intervening period of extension.

Meanwhile, however, the drying up of the continents is seriously diminishing the available habitable area, as, for example, in the Kalahari Desert, where, within the last fifty years the well-known lake Ngami has disappeared, and many river-beds have dried up.

"Roussky Vratch," December 24, 1905.

PLAGUE IN MANCHURIA.

Klognitski found cases of plague in a small settlement on the Chinese Eastern Railway, in Manchuria. The population numbered 152, and 15 persons developed plague, of whom 13 (86·6 per cent.) died.

It was impossible to trace the origin of the outbreak, or to prove that the rats or mice in the neighbourhood were infected.

"Annales d'Hygiéne et de Médecine Colonial," No. 3, 1905.

PHAGEDÆNIC ULCER.

Bouffard. The ulcer extends slowly in tissues slightly bruised, but spread rapidly when there has been severe contusion. The presence of the phagedænic bacillus is the primary cause. Secondary infection of other bacteria, usually streptococci and staphylococci are always found when the ulcer is spreading rapidly. When there is no secondary infection the ulcer tends to diminish. The ulcers last from a fortnight, at least, to three months or more. The pus from the centre of the ulcer is not inoculable when inserted under the skin or into the peritoneum of dogs, cats, gazelles, or monkeys, nor could incised or contused wounds in these animals be infected. These investigations were carried out in Somaliland. After treating over 800 cases, the author finds the best results are attained with the following treatment. Ulcers of an inch diameter are swabbed with tincture of iodine, or of perchloride of iron. They are then swabbed with 1 in 200 very hot aqueous solution of cocaine. Larger ulcers are treated with 1 in 1,000 permanganate of potash, by means of a bath for the limbs, and irrigation for ulcers on the trunk, and at night the permanganate is used in fomentation. The disappearance of the phagedænic bacillus from the ulcers is coincident with the flattening of the edges, the lessening of the discharge, the pus, from yellow in colour and of an offensive odour, becomes white and odourless, and the base is red without any necrotic tissue. When this occurs 1 per cent. solution of picric acid is used for irrigating and dressing.

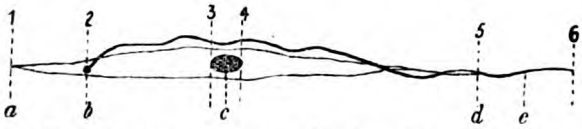
"Quarterly Journal of Tropical Veterinary Science," January, 1906.

(I.) A NEW SPECIES OF TRYPANOSOMA FOUND IN THE BLOOD OF RATS, TOGETHER WITH A NEW METRICAL METHOD OF STANDARDISING THE MEASUREMENTS OF TRYPANOSOMATA.

Lingard, A., has given the name of *Trypanosoma longocaudense* to a new species of trypanosome met with in the blood of the white-bellied house rat (*Mus niveiventir*) whose habitat is the lower Himalayan ranges. The trypanosome in question was also found in one instance in *Mus decumanus*, and some other varieties of rats, apparently hybrids. The *T. longocaudense* was never found alone in the circulation, but always concurrently with some other well-recognised species of trypanosome. The chief pecu-

liarities of the new trypanosome are: (1) The inordinate length of the posterior extremity; (2) the thread-like sinuosity of the posterior extremity of the body; (3) the abrupt end of the body anteriorly; (4) the distance of the blepharoplast from the posterior extremity of the parasite. The organism can progress with either extremity forward.

Lingard's points of measurement for trypanosoma are:—



(*a*) Posterior extremity; (*b*) blepharoplast; (*c*) nutritive nucleus; (*d*) end of body protoplasm; (*e*) free flagellum.

(II.) Observations on Bilharziosis among Animals in India.

Montgomery, R. E., describes a new species of schistosomum under the name of *Sch. indicum*, which he found in the horse and in the donkey. He gives a full description of the male and female parasite, and the anatomical lesions they cause.

(III.) Trypanosomiasis in the Camel.

Pease, H. T., deals with this subject, under the name of Tiliarsa surra (Tiliarsa, *i.e.*, three-year disease, is one of the many local names bestowed on surra disease), at considerable length. He considers that the surra of camels is caused by the conveyance of trypanosomes from infected to healthy camels by bites of the Tabanidæ.

(IV.) Through what Agency is the Trypanosoma Evansi Carried from one Surra Season to Another?

Lingard, A., points out that equine surra appears during the rainy season (June and July) in Bombay, declines during the cold season, and reaches the minimum of prevalence during January and February, and then totally disappears for a few weeks. Equines (horses, donkeys and mules) all succumb to the spontaneous and inoculated forms of surra, but domestic bovines are capable of resisting spontaneous and inoculated trypanosomiasis (*T. evansi*), and of carrying the parasite in their blood for periods exceeding a year when derived from previous cases of spontaneous equine surra. It would seem, therefore, that by these bovines surra infectivity is carried over from one season to another.

Eradication of Yellow Fever in Havanna.

Le Méhauté, Dr. (French Navy), in the course of his medical notes on the places visited during the late cruise of the French Naval Training Ship *Duguay-Trouin* to the West Indies, gives a clear and concise history of the eradication of yellow fever in Havanna, and a brief but excellent description of the organisation of the Sanitary Services—both land and maritime—of the Island of Cuba. The results of the adequate prophylactic measures taken show that yellow fever has completely disappeared from Havanna, that small-pox no longer exists there, and that the mortality from malaria has gradually decreased from 1,907 in 1898, and 909 in 1899, to 151 in 1903; furthermore, that the general mortality of the island has also been diminished, thus showing how the sanitary conditions of a country may become ameliorated under the combined action of good hygiene and judicious prophylaxis.

Malarial Infection and its Treatment.

Gros, H., Dr. (French Navy), here completes his able and careful practical study of malaria, which has been running through several recent numbers of these Archives. He now describes the treatment of chronic malaria and the methods of prophylaxis to be adopted, and lays down the lines for future preventive sanitary legislation against malaria.

On the Present Malarial Epidemics of the High Plateaux of Madagascar.

"Apropos des épidémics palustres actuelles des hauts plateaux de Madagascar." By Dr. Fontoynont, Professor at the School of Medicine, Antananarivo, D.T.M., Paris.

In the last quarterly issue of the *Revue de Médecine et d'Hygiene Tropicales* for the period ending December 31st, 1905, Dr. Fontoynont states that the belief that endemic malaria was severe on the coast-line, but essentially benign on the high plateaux, was formerly a correct one, but that nowadays this is no longer the case, and that it must be confessed that the arrival of the French in Imerina has been the starting point for deadly malarial epidemics, which for several years have shown no tendency to diminish. One fact is always at once noted by an impartial observer, and that is that malaria has not increased in severity in equal proportions amongst the natives and Europeans. Whilst the mortality is stationary—and even decreasing—with the victors, it shows, on the other hand, a very marked increase amongst the vanquished enemy.

A second fact is the progress made by endemic malaria, which is yearly advancing to the eastward, describing an ever increasing and approaching curve round Antananarivo.

How can we account for this? By two factors which, united, have reacted on each other, but which, isolated, would not have produced the same results. The first is due to the large numbers of the people who had to leave their homes and emigrate to the unhealthy regions along the coast; they there acquired malaria, and on returning afterwards to their own villages transmitted—through the intermediate agency of mosquitoes—their hæmatozoa to those inhabitants who had stayed at home. The second is the dissemination of the germs, mainly due to the Malagassy custom of "Night-guards"; in every village, at night, a number of able-bodied men, in due proportion to the number of inhabitants, are obliged to pass the night outside their dwellings in order to watch over the public safety, and to prevent attack by armed marauders; these men, wearing only a cloth garment, with their beacon light, are the marked-down prey for countless swarms of mosquitoes; and as every man must take his turn at this night duty and offer himself as a resigned victim to the bites of the Anophelina, the most practical way of propagating malaria is thus ensured—almost with the facilities of a mere laboratory experiment. In those regions where the night-guard has been put down, and where the population has not moved, malaria has remained absent, although it was on the increase in the neighbourhood. Antananarivo formerly had few mosquitoes, consequently it had little ague, but when the mosquitoes became more abundant, malaria increased; this increase was the natural consequence of a large portion of land in the very heart of the city having been expropriated for the site of a future railway terminus; this land has ceased to be cultivated, became water-logged, and afforded splendid breeding places for mosquitoes, which now began to swarm; this was soon followed by a rapid rise in the number of malarial cases, with an increasing death-roll from this cause. The conclusions to be deduced are obvious, as are also the remedies, which, to economise space, are not here reproduced (J. E. N.).

Notices to Correspondents.

NOTES ON DISEASES MET WITH IN SOUTH SYLHET, INDIA.

By A. B. Dalgetty, C.M., M.D., D.P.H.

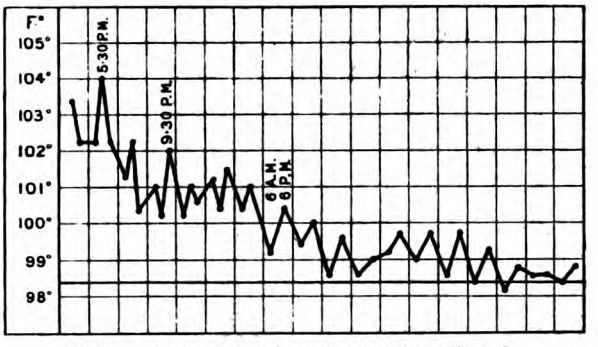
Malarial Fever, Quinine and Pregnancy.—The pregnant woman is, perhaps, not more liable to malarial fever than other people, but when she does become infected the attack is apt to be more severe, and relapses are more frequent than in others, a condition which increases the strain of pregnancy and leads to anæmia and a general low state of health. If the patient is left untreated, or if she refuse treatment, as many of the natives of India do, believing that all drugs are detrimental to the unborn child, miscarriage often occurs, either from the high temperature produced by the fever, or from the severe anæmia with its cardiac trouble and consequent dropsy.

But even in cases where repeated attacks of fever have taken place during the period of pregnancy, and have gone on right up to the time of delivery, it is remarkable how little the infant seems to have suffered thereby; as a rule, it is well nourished and normal in every respect, and, fortunately, is not born infected with the *Hæmamœba malariæ*. This fact, of the arrest of the *materies morbi* of malarial fever by the placenta is a wonderful thing, and shows that the placenta must act like a fine filter, allowing fluids to pass, but keeping back all particulate matter. It is suspected that occasionally the fœtus may be attacked *in utero*, and it is sometimes stated that infants a few hours old have shown recurrent rises and falls of temperature that appeared to have a malarial origin, and since the period of incubation would be too short to allow of a post-natal infection, one is forced to conclude that the infection took place before birth; but such cases are rare, and would seem to require further observation to confirm them, although it may well be that a placenta, damaged in some way, might allow the parasite of malaria to pass from the mother to the child.

These cases of pregnancy, complicated by malarial fever, frequently cause anxiety to the medical attendant, who fears for the safety of the mother if the fever continues, and who hesitates to give quinine for fear of causing abortion. This belief that quinine should be given very sparingly to pregnant women is widespread, and some practitioners would even withhold it altogether and treat the fever with antipyretics only; but it seems to me that the danger of producing a miscarriage by giving quinine is very much exaggerated. I hold that quinine should be given in doses sufficient to control the fever, whatever the quantity required may be, and that there need be little fear of anything untoward happening. On the contrary, one sees cases where timidity in the use of quinine may be legitimately charged with the occurrence of dangerous or even fatal symptoms in the mother, or the birth of a child immature, or showing chronic brain trouble. I have given quinine during four months in doses of from 5 to 15 grains in the twenty-four hours without any untoward result, and I believe that it is only within the last ten or fourteen days of the end of pregnancy, when uterine contractions are normally beginning to occur, and the cervix is beginning to become obliterated, that quinine may tend to stimulate these contractions; but by this time no harm will follow, even though labour be started a day or two earlier than otherwise it would have been. Pharmacology teaches that the action of a full dose of quinine upon the cardiac muscle and ganglia is to diminish the force and frequency of systole, and to lower the blood pressure, effects which, if they may be applied in the case of the uterus, would suggest a retarding rather than an accelerating influence on that organ.

Malarial Fever during the Puerperium.—The strain of parturition is apt to bring on an attack of malarial fever in a subject who has been previously infected. A febrile disturbance within the first few days after delivery always makes the medical attendant anxious, and it is a relief to know that there may be a considerable rise of temperature without serious import in a patient known to be subject to attacks of malarial fever. The following case is of some interest in this respect:—

Mrs. S., primïpara, confined at 4.30 a.m., no nurse nor doctor present. Pains came on two hours previously; birth easy, child small, no laceration of



Pulse not over 80, and respiration not affected.

maternal passage. When seen at 6.30 a.m. placenta not yet delivered, but lying loose in upper part of vagina and easily removed; condition of mother and child normal, breasts contained a little milk. On the second day the temperature began to rise, and there seemed to be a little more tenderness over the uterus than usual, but the lochial discharge was natural and free from odour, and the general condition of the patient was very good. A douche of carbolic (1-100) was now given twice a day as a safeguard, although the fever was not considered to be due to sepsis, and five grains of quinine every morning. In spite of this the temperature kept up, one day reaching 104° F., and continued with irregular remissions for about a fortnight. But during all the time the patient's general condition was very good; she could eat and sleep well, her milk came, the lochial discharge remained sweet, and the involution of the uterus was not checked. I had treated her for several attacks of malarial fever during her pregnancy, and undoubtedly this was a recrudescence of that fever brought on by parturition. The slight uterine tenderness that appeared to be present may have been caused by the fever, for I have noticed as an early sign of an impend-

ing attack of malaria that joints and muscles which had been much in use shortly before, such as the adductors of the thigh in riding, or the elbow or shoulder in tennis, were the first to ache and were more tender to the touch than other parts. The character of the temperature chart is not much help in cases of malarial fever occurring in those who live in the Tropics, for it is rarely typical, being interfered with by the frequent taking of quinine and other causes.

A Case of Chyluria.—A coolie, Sakramuni, had been on the same garden for several years, and was to all appearance in usual health, when suddenly he began to pass milky-white urine. There was no difficulty in micturition, no uneasiness about bladder, no abdominal pain, and his general condition was as good as that of his class. Physical examination disclosed nothing of note; there were no enlarged glands, the spleen could not be felt, there was no abdominal tumour, and the temperature was not raised. The urine varied in milkiness from time to time, being usually clearest in the morning, but never free from it all together. It was opaque, milky-white in appearance, deposited a thick curd-like layer half the depth of the glass, with

Sketch of Filaria Embryo, × 300, lying in midst of granular, fatty cells in urine.

Oval body in urine, possibly a developing filaria ovum.

a thinner, more opalescent layer above, alkaline in reaction and contained much albumin. There was no tinge of red in it. Microscopically it was seen that the urine was crowded with masses of highly refracting, round, granular cells, like lymphocytes, which varied somewhat in size and mostly cleared up on treating with ether; no red blood cells were seen. Naturally, one was on the look-out for the presence of filariæ in the urine, but I examined a good number of films before I succeeded in finding one. The specimen found was slightly damaged towards the head, but otherwise was quite distinct and unmistakeable, but I could not determine to what species it belonged. It was, of course, not alive when examined, as the specimen of urine had been passed several hours previously.

The foregoing drawing shows the parasite, multiplied about 300 times, lying in the midst of the granular, fatty cells.

The elongated, oval body outside the drawing was also seen, but what it represents I do not know, unless it be a developing ovum. I have not seen a drawing of the ova of the filaria in any of the books on the subject, so I may be wrong.

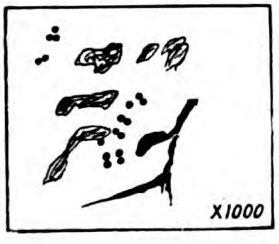
The patient went on in much the same condition, able to do his work, and showing no other signs of filarial infection for eight months. Blood films taken at this time failed to discover any filariæ in the blood either by night or day, but there was an excess of eosinophile corpuscles, as many as 11 per cent. on one occasion. At the beginning of July the urine began to be much clearer, although it still contained albumin and the same granular lymphocytes as before; and now there appeared a well-defined, lobulated swelling, occupying the right iliohypogastric region, slightly tender and giving an impression of fluctuation on deep pressure. His general health also began to deteriorate, he had fever, constipation and a foul tongue, and the blood showed a slight increase of leucocytes. An exploratory operation was suggested to the patient but his friends would not consent, so he drifted on, gradually becoming weaker, and died three weeks later of exhaustion; diarrhœa set in at the end and the urine was said to have become blood-stained. No *post-mortem* examination could be obtained. Whatever the actual pathological condition was, it would seem that the communication between the lymphatic system and the urinary channels became blocked, or nearly so, thus leading to an improvement in the condition of the urine, but being at the same time detrimental to the general condition of the patient. The lobulated tumour that developed was the result of this blocking, and probably was an enormously distended lymphatic varix, or a mass of enlarged deep iliac or sacral lymph glands. It may be mentioned that filarial disease in any form is very rare in tea-gardens in Sylhet, at any rate, the grosser manifestations, such as elephantiasis, lymph scrotum, and the like are hardly ever seen, but it may exist in masked forms, such as the condition known as circumscribed œdema of the extremities described by me in this Journal, October, 1900, and suspected to be caused by a filaria.

Cerebro-spinal Meningitis.—Hirsch, in his handbook, in 1886, says that hitherto this disease has been confined to temperate and subtropical latitudes, and that the Tropics and the Southern Hemisphere have escaped altogether. Since that time several outbreaks have taken place in different parts of the world, and notably during last year in the United States of America, but still the disease seems to remain restricted to much the same limits as Hirsch described at that date. As regards India, I have never seen any account of this form of meningitis having arisen as an epidemic, but that isolated cases do occur from time to time I think there is no doubt. At intervals during the past four or five years I have met with obscure cases which presented many of the signs of cerebro-spinal meningitis, such as muscular rigidity, retraction of the head and a deepening coma, always ending in death, but as they were always a good way off one had few chances of seeing them or of following up their history in a

satisfactory manner. The more acute symptoms of the onset and early stage of the disease are usually over before the patient is seen, and the thing that strikes one most about these cases is that they look seriously ill without evident cause; the temperature may be only slightly above normal, the pulse is slow rather than fast, there is neither cardiac nor pulmonary trouble, diarrhœa and vomiting are unusual, the absence of a wound excludes tetanus, and the symptoms are not those of sunstroke or cerebral apoplexy, yet the patient looks dangerously ill.

Not long ago I met with a less acute case which gave me a better opportunity of following up the history and the course of the disease.

Liloo, a Hindu woman, had been ill for ten days when I saw her on July 22nd, the chief complaint being severe pain in the occipito-spinal region, difficulty in walking, and general weakness. She was dull and apathetic, speech slow, pupils equal, temperature 100° F., could stand only with help, had tremors of the leg muscles, no paralysis; heart, lungs, and abdominal organs normal. Four days later the symptoms were more marked; the right arm and leg showed greater stiffening than the left, sensation in these parts was diminished, and the right knee-jerk was absent, but there was no facial paralysis and no retraction of the neck. An attempt was made to get a drop of spinal fluid, but without success at this time. Blood films did not show leucocytosis. On August 5th further developments had taken place: the patient was now semi-comatose, the head was drawn backwards and slightly towards the right shoulder, the eyes were turned upwards, outwards, and to the right, there was tightness of the hamstring muscles, but Kernig's sign was not well marked, pulse slow and very weak, respiration shallow, there was no rise of temperature, and I did not notice a skin eruption. There was tenderness along the spine, as shown by the patient shrinking when the skin was being disinfected for lumbar puncture. On this occasion I succeeded in getting a few drops of cerebro-spinal fluid. Under the microscope this showed a few flakes of epithelium, and in two specimens several micrococci were discovered; these lay together either in groups of two or groups of four amidst some particle of broken-down cells; they were rounded or oval in shape, and when stained with methylene blue had a clear space round them, but no definite capsule. I had no Gram's stain available to try its effect.



The patient gradually sank, and died on August 9th, four weeks from the beginning of the illness. A *post-mortem* examination was not made.

I have short notes of four other cases, of which two were boys, one a middle-aged man and one a young man; all were fatal, and all had the cardinal signs of this disease—sudden onset, marked depression, pains in spine, retraction of head, stiffness of muscles, ending in coma and death within a few days. In one only was the temperature high, it reached 106° F. shortly before the end.

One would like to follow up such cases as these more closely, but the lack of opportunity of seeing more of one's patients, owing often to the long distances to be traversed and the trying circumstances surrounding work in the Tropics, will be readily understood by all who have practised in hot countries.

Morbus Maculosus Neonatorum. — The following seems to be a case of this rather uncommon disease. An infant, three days after birth, developed bleeding from the mouth and anus. When I saw it on the fourth day the hæmorrhage from the mouth had stopped, but dark red blood was still oozing from the anus. The confinement had been uncomplicated, and the child had not received any injury; it looked healthy and well nourished, and showed no signs of syphilitic disease, and there was no jaundice. There was no history of lues in the parents, and there were several more children in the family, all healthy looking. Liquid extract of ergot, in 3 minim doses thrice daily, was given, and the bleeding had ceased within ten days and did not recur.

Diet and Health.—It is a common cry of vegetarians and other food faddists that flesh food is not a necessary part of the dietary of man, and they point to the case of whole races who are said to subsist on a rice diet alone, and are yet able to preserve perfect health. Like many other general statements on subjects made by those who do not have a first hand knowledge of the facts, that statement is only partly true, and it may be of interest to record my experience among many thousands of tea-garden coolies, extending over a period of nine years, with reference to this point.

I shall take anæmia, which is a general result of of many different deleterious causes, as the test of health. Anæmia is a very common trouble amongst tea-garden coolies in many parts of Assam, and sometimes becomes so rife that it seriously interferes with the work of a garden. Women, of course, suffer more than men, probably on account of the stress of pregnancy aggravating the condition, and it is no unusual thing to see a woman well advanced in pregnancy unable to stand or to lie down, and reclining in a sitting posture, with feet and legs swollen, the abdomen half full of fluid, the hands œdematous, the face so swollen that she can hardly see, the conjunctivæ and tongue of marble whiteness, bruits all over the chest, and fluid at the base of the lungs, a condition, in short, that if not soon relieved must speedily prove fatal. Nature usually sends relief by causing abortion; gradually the dropsy becomes absorbed, and in a few weeks the patient has returned to her normal state—a state, however, which is always one of relative anæmia.

That is, of course, an extreme instance, but it is by no means an uncommon one, and there are all degrees of severity leading up to that; while the men suffer almost as frequently, if a little less severely, The causes of this anæmia are various, but I am not at present dealing with them. Now, a short

acquaintance with tea-garden labourers teaches one that not all races of coolies suffer equally, and here it may be noted that Hindoo coolies differ from one another in race and language as much as a Highlander from a Cornishman, or a Welshman from a man of Norfolk; one sees that the dark-skinned coolie, such as the Santhal, who spends all he earns on food and drink, and eats fish, flesh and fowl, almost never suffers from anæmia; while the fairer-skinned coolie from the North-West Provinces, who hoards up every pice he can get, lives on food almost wholly of a vegetable kind and shuns the flesh of animals like a plague, falls an easy prey to the disease whenever his small reserve of energy is exhausted by a trifling illness.

The conditions in which these two distinct types live are absolutely identical, and both are imported from a distance to work on the tea-gardens, so that both have to become acclimatised, so to speak; the only difference lies in the nature of their food. The strong, black coolie feeds well on a mixed diet and is hardly ever a prey to anæmia, while the other, who lives on a vegetable regimen, is nearly always below par, facts that would seem to support the proposition that man best maintains his strength on a mixed diet. I am quite well aware that these two types have probably had a very different origin, that the Santhals are, perhaps, an aboriginal race, and that the coolies from the North-West have very likely sprung from a mixed Aryan stock; but for many thousands of years both have lived and worked under the same Indian sun, and it seems to me that the great difference between them lies in the nature of their diet, and that this is sufficient to explain the presence and the absence of anæmia in the two races.

Medicine and Witchcraft.—One meets with many instances of the belief in witchcraft amongst the Hindoos, and the methods employed to counteract the supposed influence of evil spirits are very interesting, although it is often difficult to get at the bottom of the matter, because the people themselves are half ashamed of their superstition, and are afraid to say much about it for fear of being ridiculed. The following incident is interesting, for more than one reason. One night, during a sharp thunderstorm, the lightning had been attracted by a papya tree, about 12 feet high, which was growing near a native hut, and striking the ground entered the house and ploughed up a zigzag furrow across the floor of a room in which two men were sleeping. The lightning had passed within two feet of the wooden bed on which they lay and most of its force had been spent in the ground, but a portion of it had glanced aside towards the feet of the two men and passed up their bodies, having been attracted, possibly, by some empty oil tins that were standing near the head of the bed.

One of the men escaped with a little singeing of the hair on his legs and chest, but the other did not fare so well. The lightning had singed him, like the other, but had then struck the right side of his head, entered the ear and stunned him. When I saw him he was still in a dazed condition but quite conscious, was able to answer questions slowly, and complained of pain in the right ear; there was a slight oozing of blood-stained fluid from the meatus, and on throwing in the light it was found that the drum was torn across. There were no gross signs of brain injury apparent then or afterwards, but he continued in a depressed state for many weeks, though he was able to go about and seemed otherwise well. Now comes the witchcraft part of it, which probably explains a good deal of the melancholia from which he suffered. Although he and his friends were quite well aware that the injury was done by the lightning, yet in their own minds they connected that physical phenomenon with a demoniacal origin. They believed that an evil spirit, or "bhoot" as they call it, had taken up its abode within him, and they recollected that a short time before he had passed a burying ground on his way home one night, and the inference was easy that some ill-disposed spirit, lurking about, had found him an easy prey, and had taken advantage of his being asleep to enter his body in that forcible fashion. So, as it was desirable to expel this unwelcome guest as speedily as possible, and seeing that the doctor sahib did not believe in such supernatural visitants and could only treat natural effects by natural remedies, the patient's friends took council together how best to attain that end.

Accordingly, they hired the services of a band, composed of drums, cymbals, and other more or less noisy instruments, formed a circle round the patient, and then let loose their witch-compelling din. At the same time one of their holy men stuffed ghee, or clarified butter, into his ears, for everything that comes from the cow is pure and sacred, and held the victim's nose over a smoking lamp of incense in order to make his quarters too hot for the demon. The "bhoot," however, appeared to be in no hurry to quit, for this performance went on for many nights, and at the end of it the patient was no better than at the beginning. Finally, I heard that he went a good distance off to be treated by someone renowned as an exorciser of evil spirits, and that after a time he returned with a lighter pocket, if not with a lighter head.

The Evil Eye.—There would be many a sudden death if a look would kill, but, fortunately, it is not so, although the belief in being "overlooked" by the "evil eye" to one's harm is not dead, and is still met in places where one would hardly expect to find it. Among Eastern peoples it still strongly exists, and the following instances will show some of the means adopted by the Hindoos to avert this evil influence. When a person receives a cut on the leg or arm, or suffers from an ulcer, one of the first things he does is to tie round the limb a cord of twisted human hair, to which, very often, a small shell is attached. The purpose of this is to prevent the sore from spreading over the limb and over the body, thereby causing death, an event which he thinks would happen if some ill-disposed person were to "overlook" him with the evil eye whilst he is suffering from his wound. It is not easy to see what disenchanting virtue can lie hidden in a snail shell or a band of twisted hair, unless the comparatively long-lasting nature of these has something to do with it.

Here is another custom practised by some, the meaning of which is explained differently by different

people. The mothers apply a black dye or pigment round the eyelids of their infants after the child is old enough to be taken out. The black substance is said to be a natural earth dug from some of the hills, but I believe any black pigment will serve the purpose. The explanation of this practice varies; some say that it is only done for looks' sake, some that it is to protect the delicate young eyes from the strong light and the glare of the dry ground, while others admit that it is done to annul the intentions of any evil-minded person who might be envious of her neighbour's pretty child and overlook it for its harm. The first of these reasons is hardly sufficient, for their dark skin throws the white of the eye into sufficient relief without the artificial aid required for that purpose by the belles of the West. The second explanation, that it protects the eyes from the glare, has something to be said for it, for I have noticed in white dogs when one eye lies in the midst of a black or brown patch, and the other is surrounded altogether by a white ground, that the former eye is strong, and free from inflammation, while the latter is very often the seat of a chronic conjunctivitis. The greater amount of pigment in the skin of the dark patch seems to diminish the irritating effects of the light and glare. However, as the black eyes of the natives rarely suffer from this cause, the third explanation would seem, perhaps, to be the right one, namely, that it protects the child against the "evil eye."

Another example may be given. When riding about one often sees near a busti, or native croft, as it may be called, a clay cooking-pot with a few white lines and circles painted over its bottom, hanging mouth downwards high up on the end of a bamboo pole; this too, I believe, is intended as a protection against the "evil eye." The design on the upturned pot, which seems always to be an old one with a black bottom, is two white lines crossing one another, with a small white circle in each of the four triangles thus formed, a rough imitation, perhaps, of a human face with four eyes, and intended to attract the glance of the "evil eye," thereby diverting its malign influence from the house and its inmates: a spell, doubtless, not less potent than ours of hanging up a horse-shoe by the door-lintel.

A possible explanation of the origin of this practice has occurred to me. When the rice harvest has been gathered in the straw is built up in round stacks which have a pole running up the centre to keep them upright. Since these stacks are never thatched the heavy rains would get in at the top around the pole, and rot the straw, and to prevent this a small clay cooking-pot is put over the top of the pole, so that the rain is diverted all round. At the end of the year, when the straw has been used up, the bare pole is left standing with its hat at the top like a very tall mushroom with a very small head, and it thus forms a rather striking object, and in course of time it would probably occur to someone looking about for a prominent point of advantage whereon to inscribe his anti-charm that here was the very thing, so that by and bye the cymbal would be set up altogether independent of its original purpose.

The Scapegoat.—The old Hebrew custom of laying the sins of the people upon a goat and turning it adrift into the desert still exists to some extent among the Hindoos, who resort to this device in order to rid their family of illness. Since a goat is rather too expensive for a poor man's purse he utilises a chicken instead. The "bhoot" which is supposed to be the cause of the person's illness is exorcised into the hapless chicken, a red mark is then put on its forehead, and it is taken well out into the jungle and allowed to escape. The disease is expected to go with it, and its former owner feels no qualms of conscience to think that some innocent mortal happening across the "scapegoat" may become a new victim. But the danger therefrom cannot be very great, for I know a sahib who once stumbled over one of these escaped chickens, and, taking pity on it, put it in his pocket and brought it home, unwitting of the risk he was running, and he is yet alive and well. Another ingenious if equally unkind device to rid one's self of an illness and foist it on another is to set down a pair of wooden shoes belonging to the patient hidden from sight at a point where two paths meet. Strings are fixed to the shoes and to wooden supports at the sides of the road, so that the first person coming along steps into the trap, the threads break, and the patient is cured of his disease at the expense of the newcomer. It is chiefly during epidemics and in long illnesses that resist medical treatment that belief in demoniacal possession gains the upper hand of the people, and compels them to resort to charms and incantations; at other times they are quite ready to seek the help and carry out the methods of modern medical science.

THE ANATOMY OF THE BITING FLIES OF THE GENERA *STOMOXYS* AND *GLOSSINA*.

By Lieut.-Colonel G. M. Giles, I.M.S. (Rtd.).

(*Continued from p.* 156.)

Of the pseudo-tracheæ of the "tongue" of the commoner flies I have as yet discovered no trace, but behind the leaf-shaped blades are two other rows of five strongly chitinised teeth of nearly as large size as those first described. Of these the one next to them has teeth with ends like that of a cheese-cutter, while the innermost has a point curiously serrated on one side, and a number of short, stout, intensely black-blue bristles may be also added, but a complete description of this wonderful structure would exceed all reasonable limits. To conclude the description of the labium, it will thus be seen that, though somewhat stiffened by its median sclerite, it is quite without any basal support, as the median sclerite tapers away to nothing at the base, and the external integument, though deceptively dense to external appearance, is really soft and flexible, and specially creased to admit of its being shortened in the same way as an accordion.

If we now turn to the upper lip or labrum, we find a structure formed exactly on the model of a hypodermic needle, and in every way as admirably adapted for piercing as the labium is obviously impossible for such a function. It differs from the familiar surgical

instrument only in the detail that the tube is incomplete, a narrow slit running along its entire ventral surface to the point, where it expands, so as to make the organ end in a point, like that of a pen. It forms, however, fully three-fourths of a complete tube, and the remaining fourth, as will be seen by reference to fig. 16, is completed by the dorsal surface of the hypopharynx. It must be remembered that all members of the fly family are provided with a similar apparatus, the difference being merely one of relative length.

Though in reality continuous with the delicate membrane that at first forms the upper wall of the tubular buccal cavity, the dense chitin of which it is composed ends abruptly at a line a little before the base of the labium, and its two corners articulate with a pair of sclerites, named by Lowne the apodemes of the labrum, which in their turn articulate with two cornua projecting forwards from the chitinous skeleton of the cephalo-pharynx, called the fulcra by the same writer. These apodemes are rod-like structures, which closely resemble the human clavicle in form; and the fulcrum is a hollow frame of chitin of rather curious form. Behind it may be taken as continuous

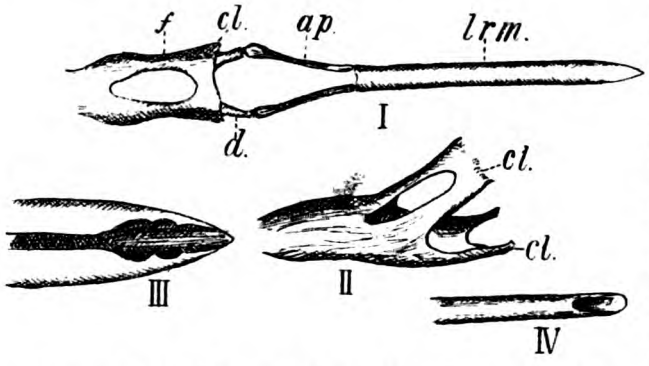


FIG. 19.—I. Semi-diagram showing the chitinous skeleton of the labrum, or upper lip: *ap*, apodeme of the labrum; *cl*, chitinous plate uniting epistome with the clypeus; *d*, distal cornua of fulcrum; *f*, fulcrum; *lrm*, labrum. II. The fulcrum drawn in perspective. III. Point of labrum; and IV., end of hypopharynx at the same higher magnification.

with the pharynx, but in front the sides are open, while the dorsal and ventral aspects are prolonged as two plates, the upper one of which turns upwards to fuse with the clypeus, and so affords an immovable connection with the chitinous exoskeleton for the front of the head. This plate is pierced by a large foramen which gives passage to the nerves and tracheæ of the trunk, and also for an air chamber continuous in front with those of the labium and behind with those of the head and of the body generally. The lower plate, on the other hand, is shaped much like the half of a butcher's tray, the handles of the tray being represented by the two cornua which again articulate with the proximal ends of the apodemes. The labrum is therefore connected with the skeleton of the head by the intervention of two joints, movable only in flexion and extension, and each capable of being moved or fixed by appropriate muscles. The point of the labrum is bevelled, and the edges of the resulting pen-like structure are each armed with two keen but not very trenchant teeth of such a form as to equally facilitate rapid withdrawal and insertion. When in function the slit in the ventral aspect of the tube is closed by the apposition of another structure, the hypopharynx. This springs from the floor of the mouth, level with the base of the labrum, and is a prolongation of the salivary duct. It consists of a delicate but fairly stiff tube, the dorsal side of which is produced laterally to form two alæ, which curve backwards in such a way as to form a fairly deep groove on its dorsal side. Seen in section (fig. 16, *h*), it is seen that the tube is comparatively small in proportion to the thickness of the walls, but it must be endowed with considerable elasticity, as was shown by a curious accidental experiment.

I had placed an entire insect in water (from spirit), with the view of dissecting the proboscis, and had spread apart its three components, when, under my eyes, the hypopharynx began to swell and lengthen, till it protruded a long way beyond the labella, and at last it snapped in the middle, after which the pieces rapidly resumed their original size. The orifice of its tube, I conclude, was in some way obstructed, and osmosis had done the rest. Sections of the entire proboscis show that the alæ fit into a curious slot in the edges of the labrum and so convert it into a complete tube through which the blood is drawn into the œsophagus.

The arrangement recalls in many ways that whereby the outer case of a cycle tyre secures itself to the rim of the wheel, which in this case is represented by the hypopharynx, but is designed to make the resulting tube withstand not positive, but negative pressure.

As already indicated, I do not believe that in *Stomoxys* the labium has any share in piercing the skin, but that it acts as a protective sheath to the more delicate lancet, and supplies the muscular force whereby the latter is driven into the skin. This, the writer believes, is effected in the following manner: By means of the various hooks and blades of the labella it attaches itself to the skin of the animal to be operated on, and then by a contraction of its powerful longitudinal muscles forcibly shortens itself, so that the labrum is made to protrude and, guided by the labella, is thrust into the skin. With a little trouble it is possible to imitate this in a fresh fly to some extent by handling the labium with the needles so as to make it lengthen and shorten. As there is no bending out of the way of the labium, such as occurs in the mosquito, it appears to the observer exactly as if the labium itself had entered the skin; the illusion being something on the principle of the stage dagger.

It must be remembered that the parts are none too large, and that any one attempting to watch the process cannot put his head too near, for fear of disturbing the fly, added to which, when animals are bitten, the fur further interferes with the possibility of seeing exactly how the operation is performed. To watch the process to any purpose would require the use of a powerful hand lens, and this is, of course, out of the question.

From the comparative point of view, the anatomy of the proboscis of *Glossina* closely resembles that of *Stomoxys*, but differs remarkedly in many details. At

their bases, the resemblance between the two proboscs is fairly complete, and the foregoing description of the chitinous skeleton of the mouth-parts might here stand almost as well for those of *Glossina*, but here the resemblance ends. A very cursory examination shows that the visible parts of the proboscis

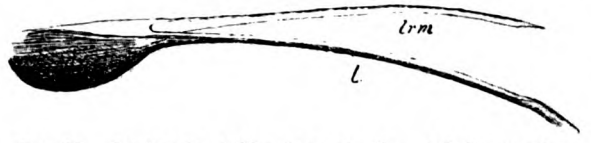

FIG. 20.—Proboscis of *Glossina palpalis*. *l*, Labium; *lrm*, labrum.

(labium) consist of two distinct parts, a large basal bulb, as thick or thicker than the base of the labium of *Stomoxys*, and a long, extremely slender rod ending in a blunt end, slightly bent backwards, so as to form an instrument exactly like a French urethral bougie. This slender part is densely chitinised and hence very stiff, but the bulb has a thin flexible integument like that of the other species. Moreover, the pair of large muscles which largely fill up the bulb, instead of remaining muscular nearly to the end of the proboscis, terminate in two delicate tendons which run through the entire slender portion to be inserted into the base of the labella.

The form of the hypopharynx and its relations with the labrum are entirely different from any other fly I have examined, and conclusively show the correctness of the general opinion that the entire slender part of the proboscis is introduced into the wound in the skin.

In *Stomoxys* and the other flies as yet examined by me, the apposition of the labrum and hypopharynx forms a tube through which the food of the insect is conducted to the œsophagus, but between these two parts in *Glossina* there is no tube, because the apposed parts are moulded to exactly fit each other.

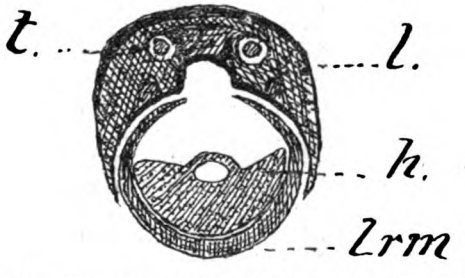

FIG. 21.—Tranverse section of the proboscis of *Glossina palpalis* at almost mid-length. *h*, Hypopharynx; *l*, labium; *lrm*, labrum; *t*, tendons of the contractor muscle of the bulb enclosed in tubular chitinous canals in the substance of the labium. *Note*.—The ventral side of this figure is uppermost.

As will be seen from the figure, the hypopharynx is a solid rod of semilunar section, with a rib running down its flat ventral face within which is the salivary canal. The convex dorsal side fits closely against the labrum, which is wrapped round it, the edges of the latter extending beyond its own, and inverted so as to form quite five-sixths of a complete tube. In somewhat similar manner the labium is wrapped round the labrum, the edges of the former overlapping those of the latter for quite a quarter of the circumference of the tube formed by their apposition. The slot on the dorsal surface of the labium therefore forms rather more than half a circle, and opposite the slit between the edges of the labrum runs a minor groove of the same width. Both walls of the labium are very thick and densely chitinised, especially in the middle line, and it it further strengthened by infoldings of chitin which support the sheaths of the long tendons of the contractors of the bulb.

The thickness of the slender part of the proboscis is less than 0·04 mm., and its length 1·4 mm.; that of the bulb 0·57 mm., and that of the part of the labium that projects beyond the labrum in the position of rest 0·17 mm.

An examination of the above drawing (fig. 20), however, shows at once that the labium, with its blunt, bougie-like end, is quite unsuited for piercing the skin, while the labrum is eminently adapted for doing so. A shortening of the length of the bulb by even a third of its length, through the action of the powerful contractor muscles, would suffice to bring the cutting point of the labrum beyond the blunt end of the labium; and assuming the latter to be fixed to the skin by means of the jagged teeth of the labella, would enable the former to make a wound into which the labium could be introduced like a probe. Once introduced, a sawing alternate action of protrusion and retraction of the labrum would enable the entire apparatus to penetrate to its full depth with comparative rapidity, as the mouth of the wound would be at the same time enlarged by the saw-like edges with which, it will be noticed, the sides of the labium are provided. The labella are smaller and certainly much more rigid than in *Stomoxys*. Judging from spirit specimens, one would say that they were anchylosed to the trunk of the labium, but probably in fresh specimens they can be separated to a moderate extent. Hausen's description and figure of the labella in Mr. Austen's monograph of the tsetse-flies appears quite accurate, and as he suggests that some part at least of their armature is brought into action by the protrusion of the elastic membrane carrying them, it seems probable that he also regards the labella as capable of but little separation.

In the position of rest the united ends of the labella form a perfectly smooth, probe-like instrument, as the somewhat complicated armature of teeth and blades, with which they are provided, are entirely hidden between them. Even when protruded, however, it is difficult to imagine any method by which they could effect a wound large enough for the organ on which they are carried to follow them.

We will now proceed to some description of the organs contained within the head.

In the middle line, just above the roots of the antennæ, will be seen a minute foramen. This is the opening of a rather extensive cavity which extends backwards under the vertex nearly half-way to the occiput, and is nearly as wide as it is long. It has also a considerable depth, and from its floor two large median processes project into its interior, besides which there are sundry median and lateral diverticula. The whole cavity has a dense chitinous wall, and is closely beset with short conical hairs. The presence

of this cavity gives rise to appearances somewhat difficult to interpret in section, unless one is aware of its existence. This cavity is the inverted frontal sac, and in the pupa is everted to form a large bulla, by means of which the operculum of the pupa case is burst open to admit of the escape of the imago, but it does not appear to serve any function in the latter, so that its significance is entirely developmental.

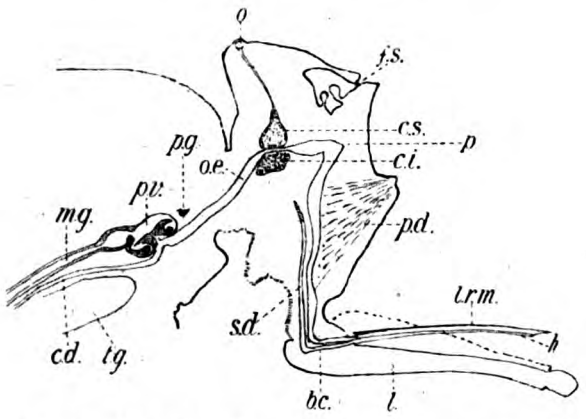

FIG. 22.—Vertical section of head of Stomoxys, semi-diagrammatic. *bc*, Buccal cavity; *cd*, duct of crop; *ci*, subœsophageal cerebral commissure; *cs*, supra-œsophageal cerebral commissure; *h*, hypopharynx; *l*, labium; *lrm*, labrum; *mg*, midgut; *o*, ocellus and its nerve; *oe*, œsophagus; *p*, pharynx; *pd*, dilatator muscle of pharynx; *pg*, proventricular ganglion; *pv*, proventriculus; *sd*, common salivary duct; *tg*, thoracic ganglion.

The buccal cavity is contained in the base of the proboscis, its anterior boundary, where the hypopharynx springs from the floor of the lower wall, being opposite the thickest part of the bulb. It is quite a narrow cavity, and is strengthened by transverse chitinous fibres, and it may be said to end and the pharynx to commence at the point where the soft flexible root of the proboscis begins. From this point the pharynx runs nearly vertically upwards in the axis of the head to a point opposite the middle of the large second antennal joint. Here it becomes the œsophagus and bends sharply backwards, in the longitudinal axis of the insect, to pierce the cerebral commissure, narrowing to an extreme tenuity, and then runs backwards and downwards through the neck to the under-surface of the proventriculus.

The pharynx is the true aspiratory organ by means of which the blood of the victim is sucked. It is of considerable size, being a quarter of a millimetre across at its widest part; but in the position of rest is a mere slit, the anterior and posterior surfaces being in contact. The slit is not, however, straight, but nearly semilunar, with the convexity backwards.

The concave ventral surface is formed of a dense plate of chitin, and is practically immovable, though it is steadied by a pair of lateral muscular bands. The anterior or dorsal surface, on the other hand, is soft and flexible, and inserted into it on either side are the powerful dilatator muscles which spring from the interior of the ridge which bounds the recess below of the hollow in which the antennæ lie.

When these muscles contract they must necessarily draw forward the flexible anterior wall of the pharynx; and as, from its density, the posterior wall cannot follow, it must needs convert the closed slit into an open cavity of oval section. In some respects the arrangement resembles that of the Culicidæ, but in them there is a localised elastic bulb which can be, like the pharynx of *Stomoxys*, actively dilated; but in that genus there can be no elastic contractility, and the return to the slit form of lumen must be through the agency of the pneumatic pressure of the great air sinuses with which the organ is surrounded.

In the above figure of a median sagittal section, the dilatator of the pharynx should, strictly speaking, not be represented, as there is a considerable interval in the middle line between the two planes of muscle, but to save an additional figure their direction is indicated by broken lines. The transverse section here

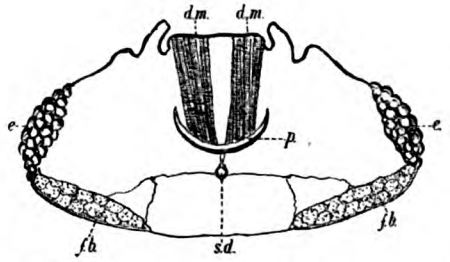

FIG. 23.—Horizontal section of head of Stomoxys. *dm*, Dilatator muscles of pharynx; *e*, lower edge of eyes; *fb*, fat body; *p*, cavity of pharynx; *sd*, salivary duct.

depicted will, however, serve sufficiently to indicate the true position of these muscles.

When piercing the transverse cerebral commissure, the œsophagus contracts to a lumen of no more than 0·015 mm.; and behind it the tube again dilates, but is compressed instead of depressed. The common salivary duct, from its origin at the base of the hypopharynx, follows the course of the buccal cavity and pharynx, at a little distance from it ventrally, and ends by dividing into the right and left ducts at a point about level with the apices of the antennæ. This is a good deal further back than as indicated by Hansen, and still more in contrast with the bifurcation in Glossina as stated by Prof. Minchin. Hansen (fig. 21, pl. 8, of Austen's monograph) also figures a large salivary reservoir.

It may be gathered from the context of his memorandum that he relied on his interpretation of the parts as seen in optical section through the integuments, and this probably accounts for the illusion, for the writer has no hesitation in stating that no such dilatation exists, as the duct has been followed in an unbroken series of sections from the hypopharynx to its bifurcation at the point indicated, and it nowhere exceeds 0·02 mm. in diameter. As far as can be made out, the spiral fibre which strengthens the duct in many diptera is wanting here. Shortly after entering the thorax the ducts cease to be chitinous and become glandular. In fig. 22 the size of the duct is intentionally exaggerated so as to make its position clearer.

The salivary ducts, after division, run together in

contact, close under the soft ventral integument of the head to the neck, and so do not follow the stomodeal canal, which is, however, accompanied in its passage through the cerebral commissure by a pair of tracheæ of about the same calibre as the salivary ducts, and by two nerve fibres.

Speaking generally, the anatomy of the head of *Glossina* appears to coincide closely with that of Stomoxys, but Prof. Minchin notes that the salivary ducts bifurcate further forwards. The most striking point about the brain of these and other flies is its large size, which must be relatively considerably larger than that of most of the lower vertebrates. There do not appear to be any details of special interest in the brain of either Stomoxys or Glossina, and as a large number of papers are easily available on the dipterous brain, any further description is quite superfluous. A very excellent account will be found in Lowne's work on the Blow-fly vol. ii., p. 453, and a shorter statement in Prof. Minchin's paper on Glossina in the *Proc. Roy. Soc.*, vol. B., 76, p. 532. Before quitting the head it may be well, however, to add a few words on the histology of the principal organs.

(*To be continued.*)

THE PURU OF THE MALAY PENINSULA.

By T. D. Gimlette, M.D.[1]

(*Continued from page* 153.)

The Varieties and Complications of Puru.

Malays distinguish the varieties of many of their diseases by a number of clinical names. For example, small-pox, which is common among them, has been given—under the name of "penyakit ketumbohan"—no less than eleven different descriptive names, according to the appearance of the pustules. Again, the average intelligent Malay will recognise at least seven different varieties of ringworm. Puru is divided in the same way into several varieties, the chief of which are: "Puru siput" or "puru kechar" ("siput" and "kechar," a shell); "puru mata kerbau" or "puru kerbau" ("mata," an eye; "kerbau," a buffalo); "puru sekam" or "puru dedak" (chaff or bran); "puru kretas" (paper); "puru kochi" (Cochin China sore); "puru tapak anjing" ("tapak," a footprint; "anjing," a dog); "puru pitis" (a small coin); also "puru parang" ("parang," a chopper) and "puru kenam." Puru of the foot is generally known as "bubol," but it is frequently referred to in Kelantan as "puru duriyan." "Bubol" has been somewhat fancifully divided into "bubol sarang" ("sarang," a nest); "bubol malai" (aigrette); "bubol susoh ayam" ("susoh," a spur; "ayam," a chicken), and "bubol bubok" (bubok," a wood maggot).

Of these Malay varieties, "puru siput" is characterised by its rupial-shaped sores, and is perhaps the most common. It is considered to be the most benign form. It is not painful, and the sores heal easily. An example of "puru siput" is shown in fig. 1.

"Puru mata kerbau" is common. The sores are very large, but heal readily. Kelantan Malays call this the real puru. It may be combined with "puru pitis."

"Puru sekan" is especially irritable with regard to itching.

"Puru kretas" is distinguished from other forms of puru by the general superficial character of the eruption. It is only skin deep, gyratory, very painful, and difficult to cure. It is the worst kind known and may cause death. It may be combined with "puru mata kerbau."

"Puru tapak anjing" is another bad kind of puru. It is very painful, and leaves large, though insignificant, scars, either similar to a dog's footprint or very irregular in shape. The sores are supposed to occur on the body, placed in the way a dog leaves marks after walking on the sands—here some and there some, and none in the middle.

Puru kochi has been mentioned under etiology. It is referred to in an old Malay dictionary as the venereal disease [16]. "Puru kochi" is said to be chronic. It is not considered fatal, although no native medicine will cure it. It is also called "puru glang besi" (glang, lit. a bracelet or anklet; besi, iron).

Puru kenam: in Kelantan "kenam" is said to occur when small children get lumps ("kenam") all over their body. It appears as circular red spots, and it is interesting to note that it is sometimes known as "puru Burma."

Puru parang is said to complicate other sores, and to be recognised by its deep ulceration. It occurs on the foot, and is said to attack old people.

There are various other unimportant so-called varieties.

Intercurrent diseases are generally the cause of death. A first attack of puru in old age is always serious. Young children may succumb, although rarely, to asthenia. Cellular abscesses may form. Scars are indefinite, but it is exceptional to find villagers who have not had puru early in life, and who cannot point in later life to some dark scar left by the disease. The old scar of "puru ibu" is well remembered by Malays, as are vaccination marks by Europeans. It resembles in appearance the scar of scalds or burns of the third or perhaps fourth degree, except that it is dark in colour. Scars are sometimes definitely depressed, and when on the face may cause contractions of the mouth known in Malay as "sipit mulut" ("sipit," puckered; "mulut," mouth). Permanent deformity of the limbs and ankylosis of joints may also be the result of puru. This disfigurement is very common, and is known as "birat" in Malay.

The Diagnosis of Puru.

Doubtless if the nature of puru were not well understood many cases of it might be classified as syphilis, because at first sight there seem to be many points of resemblance. Both rank among affections the study of which is mainly clinical; both are constitutional diseases with a period of incubation, efflorescence and decline; each is conveyed by direct inoculation, and followed in a slowly running course by the occurrence of remainders, and perhaps sequels with a tendency towards spontaneous cure. Puru is so well known to

[1] We have to apologise to Dr. Gimlette, inasmuch as we were in error announcing his valuable communication as a Craggs' Research prize essay.—Ed. J. T. M.

Malays, however, that they are unlikely to confound it with any other disease. They know that syphilis can be passed on from father or mother to their children, but hold that puru is always acquired.

The diagnosis is chiefly based on the combination of the characteristic eruption with itching, on the peculiar insensibility of the tubercles, on the general uniformity of their aspect, and on the limitation of

FIG. 1.—Mehpih—Case 1—showing the puru ibu.

the constitutional disturbance. There is only one disease—called "supia" in Kelantanese Malay, and "sang kai she toy" in Chinese—which might be mistaken for puru. This is confined to children, and occurs about the head, neck, and scalp. It appears to be similar to impetigo contagiosa, and, except for the clinical appearance of the honey-coloured scabs, to have but little real resemblance to puru. Puru does not attack the fœtus. Even when it occurs in infants before the age of eight months, it hardly ever causes an increasing cachexia with terminal diarrhœa. The peculiar hue, physiognomy and "snuffles" of syphilitic infants are wanting. The puru ibu, again, differs essentially from the primary sore of syphilis, in being generally made up of a collection of multiple tubercles which is not prone to ulcerate, but likely to last throughout the disease. This is in marked contrast to the single sloughing sore of primary syphilis as it is generally seen in Malaya. I have never seen inflammatory sore throat ("sakit kailan" or "kekail" in Malay) in puru. Polymorphism and symmetry never strike the every-day observer in any of the skin lesions of any of the varieties of puru as they may do in syphilis. Itching is the rule and alopecia the exception. Bone lesions are, I think, rare. It is difficult, indeed, to know to which stage of syphilis the Malay puru may be compared to in detail. Although, as in Case 3, a child can infect its mother with puru if unprotected, people who have had puru can contract syphilis, and others (as in Case 4) who have had syphilis can contract puru.

European practitioners must, I think, be familiar with examples of syphilis acquired by Englishmen returning home from the Malay peninsula. Puru, however, is probably unknown to them. In the one case the disease, if acquired from a Malay, is probably due to some chance infection. In the other, a European, unless converted to Mohammedanism, could never, I think, live in sufficiently close contact with Malays so as to acquire the disease for a certainty.

CLINICAL CASES OF PURU.

CASE 1. *Puru in a Malay Child.* — Mehpih, a girl, aged about 9, Kelantan villager, born at Duson Nyor in the interior of Kelantan.

Father and mother dead; no brothers or sisters. Patient was first seen at Dusun Nyor (lit. the garden of coco-nuts) on June 13th, 1905; she is said to have been ill with puru mata kerbau for more than six months. The sores are almost confined to the legs and the back and inner side of the thighs. For the most part they are soft, yellowish-white, and moist. The secretion from all the moist sores (about five or six in number) was found to be alkaline. Some of them were inclined to bleed on being scraped. The child is anæmic, bnt otherwise the general health appears to be unimpaired. She has lost the sight of the right eye owing to an accident. There is no apparent enlargement of the spleen on palpation, although malaria is very common among Kelantan children.

Puru is very prevalent in this village. Out of about forty inhabitants, fourteen or fifteen children are ill with puru mata kerbau. Examination of blood smears taken from some of them, as well as from the patient (in the forenoon), proved to be negative.

Several smear preparations made from the sores on June 13th, and again on the 21st, were stained by the Romanowsky and other methods, but nothing distinctive was found by me under the microscope beyond a number of round granular cells which stained readily with basic dyes. There were no large cells and micrococcus-like bodies which have recently been described by Surgeon-Captain James [10], Dr. Homer

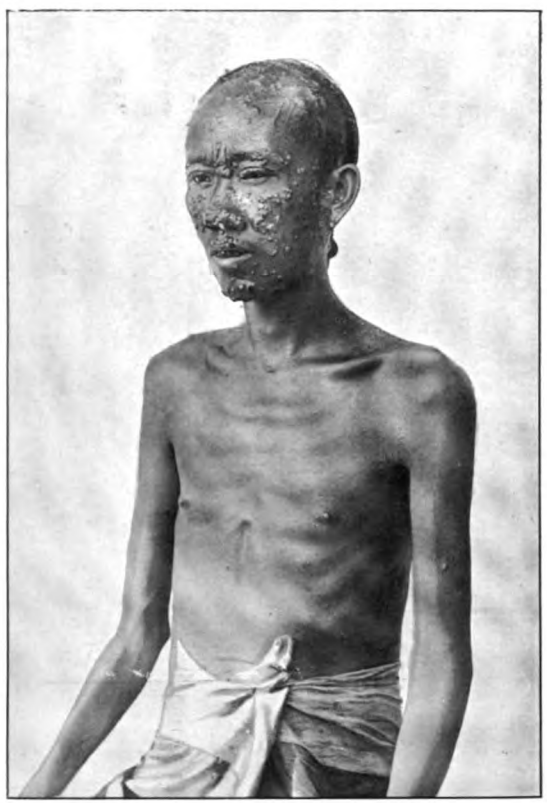

FIG. 4.—To illustrate Case 2, showing the sores of puru.

FIG. 5.—A group of Malays at Dusun Nyor, in Kelantan, showing the prevalence of puru among the children of the village.

To illustrate article by T. D. GIMLETTE, M.D., "The Puru of the Malay Peninsula."

Bale & Danielsson, Ltd., London.

Wright [17], and others, as occurring in tropical ulcer or Delhi sore. This child was treated by the local application of zinc and mercurial ointments mixed together, and when last seen on July 24th, 1905, the sores, with the exception of the puru ibu, had nearly all healed.

Case 2. *Puru in a Chinese.*—Hap Hoy, a mining coolie, native place Hong Kong, married, no children, was admitted into the Duff Development Company's Native Hospital at Kuala Lebir, Kelantan, on April 1st, 1905.

Family History.—Father died of some chest complaint about 50; mother alive and well; no brothers; one sister in good health. Has never seen any cases like his own among friends or relatives in China.

Previous History.—Emigrated from China eleven years ago, and, with the exception of malarial fever, has always been in good health.

Stayed in Singapore for five years, was in Pahang for two years, and at Tomoh for four years, when he got ill and went from there to Kelantan. He never had syphilis nor gonorrhœa; has not had sexual connection for more than twenty months; has never had a sore on the penis before. Is accustomed to take a little samshu (Chinese spirit), also chandu (opium prepared for the pipe).

States that he knows two fellow-countrymen at Tomoh who have the same disease all over their bodies, and that it is very common among the Malay children of that state. Did not live in the same house with the other Chinamen. Has eaten "budu" (a Malay condiment made of decomposing fish) when there was no better sauce to be procured.

Present Illness.—About six months ago was cutting firewood in the jungle and scratched the foot at the right ankle. A week previous had felt unwell and feverish. The ankle was painful; the scratch itched a little and presently became sore. Four or five sores then developed, and in about forty days they coalesced and reached their present horseshoe shape and size, which is (April 5th, 1905) 6·35 cm. by from 2·54 cm. to 0·63 cm. Later on the foot was painful on walking any distance. A month afterwards again felt feverish, and the eruption came out on the forehead and scalp. A sore came next on the left side of the prepuce; it itched and he scratched it. In two months' time sores had formed on the right side of the prepuce. Up till now he had continued at work, but then the sores attacked the nose and eyelids. The nasal sores spread out gradually at the nostrils until they reached their present size, namely, on April 5th, 1905, nearly 10·16 cm. by 1·9 cm. Had then to stop work as a mining coolie on account of pain in the bones and in the joints, and decided to come to Kuala Lebir. The sores are now (April 5th, 1905) drying up. No fresh ones have appeared for about a month. The last to appear were on the back.

On Examination.—The eruption is known in Malay as puru, and it has the characteristics of the disease as shown in fig. 4, which was taken on April 3rd and 5th, 1905. There is no apparent enlargement of liver or spleen. There is sympathetic femoral bubo in the right groin, but it is unlikely to suppurate. No other glandular enlargements. The foot sore is suppurating under a thick scab. The discharge is acid to litmus paper, but that from the sores on the penis and forehead is alkaline. Two tubercles were removed from the back under cocaine, as well as one from the prepuce. Prior to examination, these nodules were placed for twenty-four hours in 30 per cent. alcohol (in filtered water), then for the same time in 70 and 90 per cent., and finally in absolute alcohol. The result of the microscopical examination is given under the heading of pathology.

The sores were dressed with Scott's dressing and a mixture of iodide of potash, 5 grains, three times a day, administered by the mouth. The sore on the ankle was dressed with chlorinated soda lotion.

By the end of the month a great improvement in the general health had taken place. The pains in the limbs and joints had entirely ceased. On May 25th another tubercle was removed from the hairy part of the chin, and carbolic acid, pure, was applied to the cut surface, because it seemed as if puru sores were forming at the site of the former incisions. They all healed naturally, however, in the end. In June, the iodide was increased in dose to 10 grains and 5 minims of liq. arsenicalis were added to the mixture. The patient improved daily, but only up to a certain point. He was next given mercury internally, the liq. hydrarg. perchloridi, in half-drachm doses for two weeks, but as he appeared to be still losing ground under this treatment it was discontinued, especially as some of the old eruption (which had apparently been cured) began to recur. Various local applications were then tried, including the application of tincture of iodine, ichthyol vasogen, thymol ointment, and white precipitate ointment, but without much success. He was finally treated with zinc and mercury ointment alone, and appeared to derive most benefit from it.

On Alternation of Generations and Change of Host in Trypanoplasma Borelli (Laveran and Mesnil).

Keyoselitz, Gustav. This is a long and very complete memoir, covering much the same ground as has been described by Brumpt, though the author differs from the latter in many points, notably in regarding the species found in a variety of freshwater fishes as all referable to the above species, the intermediate host being the leech, *Pisciola geometra*. Both the fish and the leeches often succumb to the infection, the most striking symptom in the fish being anæmia, while the colour of the leeches alter and their clitellar region becomes swollen.

He never once succeeded in infecting one fish from another even of the same species, and believes that the supposed successes of other authors were really cases of relapse of an old natural infection, and, though he was equally unsuccessful in his attempts to infect fish through the agency of the leeches, he describes in great detail a cycle of evolution which closely follows that described by Schaudinn in the case of *Trypanosoma noctuæ*, so that under natural conditions it is probable that this leech acts as a true intermediate host, and forms the agent of infection. For fuller abstracts of this paper *vide* F. Mensil in the *Bulletin de L'Institut Pasteur*, April 15th, 1906.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,	5/-;
100	,, ,,	6/-;
200	,, ,,	7/6;
50	Copies beyond four up to eight pages,	8/6;
100	,, ,, ,,	11/-;
200	,, ,, ,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

PROFESSOR ELIE METCHNIKOFF.

(The Harben Lectures.)

THE Royal Institute of Public Health has from time to time brought distinguished men from several parts of Europe to London to deliver the Harben Lectures. The course for this year has been given by Professor Metchnikoff, of the Pasteur Institute, Paris, and it is scarcely necessary to add that a great scientific treat has been afforded us. The subjects chosen for the three lectures were, on May 25th, "The Hygiene of the Tissues of the Organism," on May 28th, "The Hygiene of the Intestinal Tract," and on May 30th, "Syphilis."

In the lecture on "The Hygiene of the Tissues," Professor Metchnikoff expounded his views in a condensed form, and defended the service the phagocytes render in procuring immunity, a service which is being largely claimed for a soluble substance circulating in the blood and met with in other body liquids—the opsonin of Wright.

This advocacy of a humoral action is based on the belief that microbes in the blood must be impregnated with opsonin before the phagocytes can attack them and destroy them. The *rôle* the phagocyte plays in the destruction of pathogenic microbes, if this belief be true, is only of a passive character, and dependent on the preliminary action of the opsonin. Metchnikoff is not inclined to acknowledge the superior potency of opsonin in comparison with the phagocyte in procuring immunity. He states that there can be no doubt that, under artificial conditions, and outside the body when the phagocytes are weakened they do not show their functional activity to such advantage as inside the body; but left to themselves in a liquid deprived of all opsonic substances, the phagocytes surround the microbes, only instead of doing this in a quarter of an hour, it takes them perhaps an hour or two to accomplish the act.

That the living body remains apparently healthy in spite of its containing pathogenic microbes would appear now to be a fact. A man may be the host of diphtheria bacilli, cholera vibriones, the *Bacillus typhosus*, and other bacteria, without necessarily developing the corresponding diseases. It is even possible to introduce tetanus spores into an animal so peculiarly sensitive to tetanus as the guinea-pig without the animal acquiring the disease. When, however, the guinea-pig so infected is placed under unfavourable conditions, as by exposing it to a very high temperature, the resistance of the animal is overcome and the disease asserts itself.

Human beings may serve as bacilli carriers without they themselves being the subject of the disease which the bacilli may give rise to in others; this fact is of superlative interest and importance in the study of epidemiology, and is one calculated to divert our attention to other sources of infection than to those we are accustomed to view with suspicion, such as milk, water, and other articles of food and drink.

Metchnikoff sums up his conclusions on this subject by stating that all observations on immunity against infective agents points to the belief that this phenomenon is the result of phagocytic action, or, in other words, that immunity is a function of the cells. Of substances which hinder phagocytic action, opium and alcohol are perhaps the chief, but he also inculpates quinine as a poison to the white blood cells. Increased resistance towards pathogenic microbes is a department of prophylaxis which promises to play an important part. Issaeff, some ten years ago, showed that increased resistance could be procured in guinea-pigs by injecting these animals with such liquids as normal saline solution, urine, and serum. R. Petit has recently employed heated horse serum in his gravest operations. In a case of abdominal section on a woman, on whom he operated for multiple fibromata of the uterus, complicated by inflammation of both adnexa and by suppurative pelvic peritonitis, Petit poured into the abdominal cavity before suturing the abdomen about 30 grammes of heated horse serum with successful results. Several other surgeons have followed Petit's example, and in cases of abdominal and pleural operations the use of heated horse serum has been eminently satisfactory. Miculiez, by introducing subcutaneously injections of a solution of nucleinic acid twelve hours before operation, showed that an increase in the number of white blood corpuscles in the blood occurred, reaching, in one instance, to as many as 24,000 per cubic millimetre.

Whether it be heated horse serum, a nucleinic acid, or other substances that are employed, Metchnikoff considers that they all act in one way. The influence they exert is not brought about by an increase in the sensitising substances nor by a production of opsonins, but by enhancing the phagocytic reaction.

By the establishment of the thesis that the phagocytes are our arms of defence against the infective germs which beset our bodies, Metchnikoff contends that the first step forward in the hygiene of the tissues has been made, and that a secure foundation stone has been laid on which to build our knowledge and experience.

MALARIA IN CUBA AND PANAMA.

W. C. Gorgas, M.D., Chief Sanitary Officer, Canal Zone, Panama, stated at the annual meeting of the American Society of Tropical Medicine on March 24th, 1906, that while the percentage of fatalities is not nearly so great as from some other tropical diseases, the amount of incapacity caused by malaria is very much greater than that due to all other diseases combined. He drew attention to the deleterious effect of unchecked malaria upon soldiers during a campaign.

The effect of the eradication of mosquitoes, upon the number of cases of malaria was very noticeable in Havana. For many years the average number of deaths from malaria amounted in Havana to 350; in 1901, the first year of the anti-mosquito campaign, the number of deaths from malaria amounted to 151 only; in 1902 there were 77 deaths from the disease; in 1903 about 50, and during subsequent years it averaged about 40. In the hospital at Ancon, Panama, in the six months ended March, 1906, Colonel Gorgas had personally treated 1,055 cases of malaria with only five deaths. The Æstivo-autumnal variety predominated, and quinine was the invariable mode of treatment. Of twenty cases of hæmoglobinuric fever in the eight months ended March, 1906, only three died.

Persia.—Plague continues in epidemic form in Eastern Persia (May 29th).

Arabia.—Plague has been declared at Jiddah (May 30th).

Egypt.—During the week ended April 15th, 35 cases of plague were recorded in Egypt, chiefly in the Minieh and Keneh provinces.

Reviews.

The Nature and Treatment of Cancer: Some Methods of Hypodermic Medication in the Treatment of Inoperable Cancer. By John A. Shaw-Mackenzie, M.D.Lond. Third edition, revised and enlarged. London: Baillière, Tindall and Cox, Henrietta Street, Covent Garden, 1906. Pp. 99. Price, 2s. 6d. net.

Every practitioner will welcome this concise account of the treatment of cancer by modern methods. The principal remedies dealt with are Chian turpentine, soap and ox-gall, and trypsin. The results given are, to say to the least of them, encouraging.

The Animal Parasites of Man. A Handbook for Students and Medical Men. By Dr. Max Braun. Third, enlarged and improved edition, with 294 illustrations in the text. Translated from the German by Pauline Falcke. Brought up to date by Louis W. Sambon, M.D., Naples, and Fred V. Theobald, M.A. London: John Bale, Sons and Danielsson, Ltd., Great Titchfield Street, Oxford Street, W., 1906. Price, 21s. net.

Parasitology is assuming so important and prevailing a position in medicine that for several years to come it will be assigned the foremost place amongst the several accessory departments of scientific research and study. It is essential, therefore, that an authoritative text-book should be in the hands of medical men.

Dr. Max Braun's well-known work on the "Animal Parasites of Man" has, it is to be feared, been capable of being read by only a very few practitioners owing to lack of knowledge of German, and we are thankful to the translator and to the publishers, who, at a great sacrifice of time and of money, have now given us an English edition of this important work.

Braun's work is the best book on the subject, and it has been translated by Miss Falcke, on whom we, in this country, have come to largely rely for accurate translation of German medical and scientific books into English.

The chapter on parasites in general is a liberal education in itself, and were the student of general medicine to advance no further than this chapter in his reading he would be placed in a position to grasp the importance of the subject, and to lay a foundation on which to base a scientific knowledge, so as to enable

him to enquire more carefully into any branch of the subject he may be interested in.

The protozoal, the primitive, parasites, are in many ways, perhaps, the most interesting; chiefly on the ground that they are of all parasites the most closely studied at the present time. Amongst the protozoa we find the rhizopoda, of which the various amœba are best known; the flagellata, represented by trichomonas, cercomonas and trypanosoma; the sporozoa, of which the gregarinida and the large group coccidiida are of high importance, and yet better known the *Plasmodium malariæ* of Laveran. The flat-worms (platyhelminthes) and the thread-worms (nematodes) are more familiar to the general reader, and the student of tropical medicine will take special interest in the filaria and the ankylostoma. Of the various groups of arthropoda, the arachnoidea, from the fact that the several species of argas and of ornithodorus are included amongst them, are of special interest at the moment. A separate chapter is devoted to mosquitoes and the various flies, including the tsetse-flies.

The illustrations are clearly represented and their accuracy incontestable. The study of parasitology is yet in its infancy, but before its literature becomes too voluminous it would be well for present-day students to master the contents of this book so that the subject may be readily understood and followed. We are indebted to Dr. Sambon for his careful revision of the chapters on protozoa, cestodes, and nematodes; and to Mr. Theobald for his exposition on the trematodes, arthropoda and several other sections of the work. We congratulate the publishers upon the general appearance of the book and for supplying us with a clearly printed text.

The thanks of the profession are due to the publishers, the translator, and to Dr. Sambon and Mr. Theobald, for placing within our reach an authoritative text-book on an important subject.

Drugs and Remedies.

HELMITOL, a powerful urinary antiseptic, is a preparation of the Bayer Company, Limited, 19, St. Dunstan's Hill, London, E.C. In the treatment of cystitis, fœtid urine, and in troubles associated with enlarged prostate, it is excellent. In gonorrhœa helmitol internally, combined with local injections of protargal, is efficient.

SOLUROL (thyminic acid) in 3 or 4 grain doses daily after meals is a new remedy for gout, introduced by Allen and Hanbury, Limited, 37, Lombard Street, London, E.C.

Notes and News.

AN "At Home" at the Royal Albert Dock Branch of the Seamen's Hospital Society, on Saturday, May 19th, was attended by about 200 executive officers of all the London and many provincial hospitals. The occasion was the completion by Mr. P. Michelli, Secretary of the Seamen's Hospital Society, of his year of office as President of the Hospital Officers' Association, and amongst those present were Sir Francis Lovell, Sir Frederick Young, Capt. Tunnard, Mr. Keith D. Young, the Society's architect; Mr. W. R. Pite, architect to the new King's College Hospital; Dr. Harford, of Livingstone College; Dr. C. C. Choyce, Medical Superintendent of the Dreadnought Hospital; Capt. Worlidge; Mr. Walter Alvey, Honorary Secretary Hospital Officers' Association; and Mr. Charles T. Walrond, consulting engineer St. George's Hospital and the Children's Hospital, Great Ormond Street, and several others. The Hospital and the London School of Tropical Medicine in connection therewith were open to inspection, details of the building being given by Mr. Keith D. Young. A lantern demonstration was given in the theatre of the School and a demonstration of microscopic specimens of the parasites of malaria, sleeping sickness, &c., was given by Dr. Stanton in the laboratories. Speeches were delivered by Sir Frederick Young and others, and opportunities were afforded for visiting vessels of the P. and O. and Ocean Lines.

SPREAD OF LEPROSY BY INSECTS.—Dr. W. T. Goodhue, Superintendent of the Molokai Leper Settlement, states that he has found the *Bacillus leprœ* in the female mosquito—*Culex pungens*—and in the bed-bug—*Cimex lectularius*. The fact that the leprous bacillus has been found in insects is not, we believe, new; what we are anxious to know is whether these insects play a part as intermediate hosts, and what cycle of evolution, if any, takes place in their economy.

W. C. GORGAS, Chief Sanitary Officer, Isthmian Canal Commission, Panama Canal Zone, in a report dated Ancon, April 16th, 1906, states: The health conditions continue excellent. No quarantinable disease occurred in the Zone during March. No case of small-pox has occurred within the last year. The last case of plague occurred seven months ago, and the last case of yellow fever over three months ago. Among the 25,000 employees we had 78 deaths, 10 among the whites and 68 among the negroes. Of the 10 whites 5 were from the United States. Of these 5 only 3 died from disease, 1 from pneumonia, and 2 from dysentery. The two principal causes of death among the employees were malaria, 22, and pneumonia, 17. The disease that caused the next highest death-rate was dysentery, 8, and the next after that accidental traumatism, 4. The March in which the French had the largest number of employees on the Isthmus was the March of 1885, when they had 16,755 men on their rolls. During that month they had 9 deaths from yellow fever in Ancon Hospital. How many deaths occurred outside of that hospital they had no means of finding out. During March of 1906, with our force of 25,000 men, which is the largest we have had, we had not a single case of yellow fever on the whole isthmus. But the best measure of the health of a body of men is the average number daily

sick. We had in our hospitals from our 25,000 employees, on each day for the month of March, an average of 491 sick men, which would give us a rate of 19·65 per 1,000, an exceedingly good showing.

COLONIAL NURSES DECORATED. — Mrs. Duncan Urquhart and Miss Margaret Graham have been decorated by the Order of St. John of Jerusalem in England. Their names were brought to the notice of Mr. Chamberlain, then Colonial Secretary, by the Principal Medical Officer of Southern Nigeria, for the excellent work they did during the recent expeditions and for the devotion and self-sacrifice shown by them on all occasions. Mrs. Urquhart and Miss Graham have been admitted honorary nursing sisters and are entitled to wear the Maltese Cross of white enamel of the Order of St. John.

MOSQUITOES.—*Culex solicitans* will breed in no other place than salt water. To get rid of this mosquito it is necessary to drain the salt-water swamp lands along the coast where this mosquito prevails.

TRACHOMA IN MONTREAL.—Amongst 1,000 emigrants from Europe, one half of which were composed of Russian Jews and Syrians, 150 cases of trachoma were found.

Personal Notes.

COLONIAL MEDICAL SERVICE.

Dr. Derwent Waldron, Senior Medical Officer, Gold Coast Colony, has arrived in England on leave of absence.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Transvaal Medical Journal," March, 1906.

Maynard, G. D. "Some Observations on the Protozoal Diseases of the Blood, with Special Reference to the *Piroplasma Bigeminum*."

Of forty-five cows inoculated with the blood from a heifer which had recovered from an experimental attack of red-water disease, 4·4 per cent. died. Of forty-three cows in the same herd which were allowed to contract the disease naturally, 11·7 per cent. died. The cows showed a reaction (first) on the tenth day, and also a reaction (second) on the twenty-fifth day after experimental reaction. In regard to the appearance of *Piroplasma bigeminum* in the red corpuscles, Maynard is of opinion that when two parasites appear in a cell the explanation is to be frequently found, not in the division of an originally single parasite, but in a double infection by two young parasites. The two parasites may be gametes about to conjugate to form a zygote, so that a sexual cycle, as well as an asexual cycle, might be assumed to occur in the one host. A prolonged observation, however, failed to demonstrate any union of pairs, but on the other hand, the mother parasite extruded from its substance a small mass of protoplasm which grew in size, and finally became free from the parasite and the red corpuscle in which the parent was contained. In addition to the extrusion of these daughter cells the parent parasite also undergoes several divisions within the red corpuscles before the daughter cells are extruded. The frequent appearance of two chromatin masses in the pear-shaped parasite seems to suggest a nuclear division prior to conjugation. The possibility, therefore, of a sexual as well as an asexual cycle in piroplasma infection would seem a feasible interpretation of the phenomena observed, and of the clinical symptoms and behaviour of this disease generally. From the fact that conjugation in certain forms of the tertian malaria parasite has been stated to occur, Maynard suggests that the peculiarities of malignant malaria seem to demand some such interpretation not accounted for by the theories explaining the symptoms of simple malaria.

"Journal of the American Medical Association," March 24, 1906.

Vedder, E. B. "An Examination of the Stools of 100 Healthy Individuals, with Special Reference to the Presence of *Entamœba Coli*."

The *Amœba coli* has been found by Schaudinn, Craig and others in from 20 to 65 per cent. of the stools of healthy individuals in different parts of Europe. Vedder, from observations made in the Philippines, recently found that of Americans in the Philippines 50 per cent., and 70 per cent. of the natives of the Philippines harboured the parasite. As these were healthy persons the observation helps to confirm the belief that the *Amœba coli* is not a pathogenic factor in the production of dysentery.

Vedder classifies the characteristics of the dysenteric and of the normal amœbæ as follows:—

Entamœba Dysenteriæ.	*Entamœba Coli.*
SIZE.	
25-30 microns.	(Not a distinguishing feature.) 10-20 microns.
SHAPE.	
Usually some other shape.	Spherical when resting.
COLOUR.	
Greenish.	Opaque greyish.
PROTOPLASM.	
Ectoplasm and entoplasm *easily distinguished.*	Ectoplasm and entoplasm *distinguished with difficulty.*
Ectoplasm very refractive.	*Ectoplasm not refractive.*
Ectoplasm finely granular.	Entoplasm homogeneous.
Entoplasm coarsely granular.	Entoplasm finely granular.
PSEUDOPODIA.	
Large and easily distinguished. Certain ectoplasm and entoplasm.	Entirely ectoplasm. Hard to distinguish.
VACUOLES.	
Many vacuoles.	Vacuole absent usually. Never more than one.
NUCLEUS.	
Often absent. When present structure of nucleus hidden except in stained specimens. Nuclear membrane not well defined.	Almost invariable, with well-defined nuclear membrane and other structure.
Changes position markedly.	In moving organism retains its relative position.
RED CORPUSCLES INGESTED.	
Many.	None observed.
MOTILITY.	
Great progressive motility.	Often absent, and when present, of limited extent and short duration.

"Il Policlinico," Rome, May, 1906.

THE CEREBRO-SPINAL FLUID IN CERTAIN CASES OF PERNICIOUS FORMS OF MALARIA.

"Il liquido cefalo-rachidiano in alcuni casi di perniciosa malarica." By Dr. Nicola Pende.

According to Dr. Pende the study of the cerebro-spinal fluid in malarial infection has been entirely overlooked, which is the more remarkable as the examination of this

liquid is now undertaken in nearly all morbid processes complicated by severe nervous symptoms, from which list malarial infection cannot well be excluded.

Two indications are now specially sought for in the study of the cerebro-spinal fluid. The one is essentially a clinical one, or an aid to diagnosis; the other is essentially a scientific one, relating to the physio-pathology of the cerebro-spinal fluid, in the hope of finding therein a key to the mechanism of the symptoms due to the neural axis. With this double object in view, Dr. Pende undertook some researches on the cerebro-spinal fluid in malarial cases, restricting himself for the present to the more severe forms of the disease, *i.e.*, the pernicious forms. The severity and diffusion of the æstivo-autumnal attacks which were recently noted in the Roman hospitals supplied him with many cases for observation; nevertheless, in many instances, he experienced some considerable difficulty in obtaining the fluid, either because the pernicious condition of the patient was a contraindication for the lumbar puncture, or because the quantity so obtained was insufficient, or was not perfectly clear owing to the admixture of blood. For these reasons the present remarks apply only to five cases of pernicious attacks of malaria, specially selected for their nervous symptoms.

Each examination of the cerebro-spinal fluid included not only the cito-diagnostic formula, but also, as far as possible, the principal physico-chemical properties. A bacteriological examination was unnecessary owing to our certain knowledge of the etiology of malaria; in each instance the following were specially sought for:—

(1) The state of compression of the fluid.
(2) Appearance and chromo-diagnosis.
(3) Density.
(4) Crioscopic point.
(5) Hæmolytic power.
(6) Amount of albuminoids.
(7) Fibrinous reticulum.
(8) Amount of chlorides.
(9) Sediment, especially with regard to the cito-diagnostic formula.

The fluid extracted never exceeded 20 cc. The cases occurred in women of all ages, who were received between June and December, 1905, into the Hospital of St. John Lateran. A series of control experiments, conducted on the identical lines, were carried out in perfectly normal cases who had been admitted to the surgical division of the same hospital.

For the study of the compression of the cerebro-spinal fluid a special form of manometer was used. The crioscopic point was determined by Beckmann's apparatus; Bard's process was employed for studying the hæmolytic power; the amount of chlorides was obtained by the Wolhard-Salkowski method; lastly, for the cito-diagnostic examination, Nikiforoff's reagent was employed for fixing the slides, which were then coloured with thionin or with hæmatoxylin and eosin.

The results obtained from the examination of the cerebro-spinal fluid of healthy women was as follows:—

The pressure varied enormously; the density was 1007 to 1010; the congesting point = 0·65; albumen, constantly present; percentage of chlorides, 0·8 per cent.

Some clinical notes on the several cases of pernicious attacks now follow, but want of space prevents their insertion here.

* * * * *

As a result of these observations, Dr. Pende states that the cerebro-spinal fluid may present, in certain cases of pernicious malarial attacks, alterations both in its physico-chemical properties and in its cito-diagnostic formula.

One constant feature was noted in all the cases, viz., a more or less diminution of osmotic tension. It is important to note that the hypotonic condition of the cerebro-spinal fluid has, until now, been considered almost pathognomonic of meningitis, whether tubercular or cerebro-spinal, but as has been seen, this same hypotone may be found also in the severe nervous forms of malarial infection.

In two of the cases lymphocytosis was superadded. Thus malaria in its severe forms has to be added to the somewhat lengthy list of morbid processes, accompanied by lymphocytosis of the cerebro-spinal fluid.

The percentage of chlorides in the majority of cases was diminished.

As regards the chromo-diagnosis, in one case the liquid was yellowish, and in another it showed a bright green fluorescence.

Dr. Pende considers the serious disturbances which the cerebral circulation undergoes, owing to the heaping-up of the parasite-infected corpuscles in the capillaries, as sufficient to explain the origin of the above-mentioned modifications. The alterations of the endothelium of the capillaries and the obstruction of many of these by parasitiferous thrombi may be the cause of some of the blood elements passing from the capillaries themselves into the perivascular lymphatic spaces, and from these into the arachnoid cavity, which elements may produce the diminution of the molecular concentration of the cerebro-spinal fluid, or the presence of blood corpuscles, or lymphocytosis, or yet again, the presence of pigment, and perhaps also of toxic substances already existing in the circulating blood.

As to the question whether the alterations of the fluid can enter into the pathogenic mechanism of the nervous symptoms of pernicious fevers, little as yet can be said definitely, for the physio-pathology of the cerebro-spinal fluid has not yet furnished us with sufficient experimental or clinical data to solve this problem. J.E.N.

"Centralb.. f. Bakter.," 1, Origin., T. xl., p. 290.

RESEARCHES ON BACILLARY DYSENTERY.

Ludke, H. The author has studied the agglutinins and precipitins of the bacillus of dysentery. Their behaviour, when treated with strongly agglutinating serums of the Shiga-Kruse and Flexner bacilli respectively, leads the author to believe that the latter is a variety of dysenteric bacillus which appears only in certain epidemics.

SUBHEPATIC ABSCESS.

By James Cantlie, M.B., F.R.C.S.

The classification of abscesses of the liver, which for the past ten years I have adopted as a means of clinical differentiation, would appear to hold good as experience extends. The terms suprahepatic, intrahepatic, and sub- (or infra) hepatic abscesses have more than a mere anatomical or descriptive convenience and significance, more even than a clinical import, for investigation has served to establish a pathological basis of some reliability.

The examples of subhepatic abscess which have come under my notice have been few, five in all, four of which occurred in patients of my own. By a subhepatic abscess I do not merely mean that pus from the liver has simply pushed its way downwards to the under-surface of the liver, and there opened into a neighbouring organ or into the peritoneal cavity, but that the abscess originated on the under-surface of the liver, between the peritoneum and the liver substance, and involved the neighbouring liver tissue secondarily.

In three of the five cases of subhepatic abscess, the pus drawn off at the operation was proved to be sterile. This is in no way characteristic or exceptional, for in 32 out of 47 suprahepatic abscesses I have operated upon the pus has also been found to be sterile. On the other hand, the abscesses originating intrahepatically have almost, without exception, been proved to contain bacteria in the pus drawn off when the abscess is first opened. I do not refer to the amœba, which we meet with in the wall of every collection of liver pus, as it is in the wall of most abscesses connected with the abdomen, and is therefore without specific pathological significance.

A subhepatic abscess may occur in persons who dwell in the Tropics or who have never been out of Britain. Of the cases in question the habitat of the patients was as follows:—

No. 1, an American sailing ship captain, who, whilst his ship was lying in Hong Kong harbour, developed a subhepatic abscess. No 2, a lady who had resided some years in Alexandria. No. 3 a man who had never left Britain. No. 4, a sailor who belonged to the Royal Navy. No. 5, a man who had never left Britain. Subhepatic abscess has no pathological relationship with dysentery or any form of intestinal flux, although in two of the cases the patients confessed to diarrhœa but not to dysentery.

In four of the cases the collection of pus was on the under-surface of the right half of the liver, to the right of the gall-bladder; in the fifth case the under-surface of the left half was involved.

History of a Typical Case of Subhepatic Abscess.—The patient becomes conscious of a discomfort in the neighbourhood of the right rib cartilages, intermittent at first but in time becoming more persistent; the discomfort is most marked during the day, and lying down affords relief. As a rule the pain is referred to the neighbourhood of the gall-bladder, and at first, and indeed later, the signs and symptoms appear to indicate gall-stones, or an inflammatory affection of the gall-bladder. Occasional attacks of fever, passing off in sweats, occur, and if the patient has been in a subtropical or tropical country, malaria may be (and has been) suspected to be the cause. The indefinite nature of the ailment leads to delay in diagnosis and to the necessary treatment; for a tender spot with some fulness beneath the right rib cartilages may be ascribed to kidney, liver, gall-bladder, pancreas, or bowel. The mobility of the swelling points to the possibility of a movable kidney; the general disturbance with pain in the region of the liver suggests hepatitis or perihepatitis or hepatic abscess; the situation and shape of the swelling, the local pain, and the fever accompanying the condition, would seem to definitely point to a cholecystitis; but malaria, malignant disease of the hepatic flexure of the colon, pancreatic cyst and hydatid, have each and all been suggested as explanations of the indefinite clinical signs and symptoms which obtain when a collection of subhepatic pus occurs.

The further general signs and symptoms it is needless to recount, a collection of pus anywhere in the upper part of the abdomen will give rise to occasional vomiting, furred tongue, loss of appetite, a markedly fluctuating temperature, rigors, sweatings, disturbance of the bowels now loose now constipated, and so on. There is no one sign or symptom, when a swelling occurs in the epigastrium or right hypochondrium, that can determine the diagnosis, nor any group of signs or symptoms which may not bear in the present state of our methods of clinical diagnosis, a plethora of interpretation.

Given, however, a distinctly painful spot on the under-surface of the liver associated with constitutional disturbance and pyrexia, and, it may be, a blood examination suggesting pus, an exploratory incision ought to be made without hesitation.

Case 1.—Captain of a sailing ship, aged 42, plying between New York and Hong Kong, developed a subhepatic abscess. The captain lived on board ship, which had been lying in Hong Kong harbour from November to March before the abscess was detected. The patient was operated upon with the idea that he was suffering from cholecystitis. When the abdomen was opened a sausage-shaped swelling was found lying parallel to and 1½ inches to the right of the gall-bladder. The wall of the abscess cavity was stitched to the abdominal wall and the abscess cavity opened and drained. The abscess extended almost the whole breadth of the liver in an antero-posterior direction. The patient returned to his ship in twelve days, sailed on the thirteenth day, and only withdrew the drainage tube some six weeks later whilst on the voyage. He made a perfect recovery.

Case 2.—A lady, aged 31, married, one child, had had several attacks of "fever" and diarrhœa in Egypt. When seen in London there was a movable swelling between the right hypochondrium and the right lumbar regions; the spleen was enlarged, the liver dulness increased downwards, febrile attacks with irregular temperature and malarial parasites in the blood. I diagnosed the case as one of malaria with movable kidney. Subsequently, when the swelling was exposed, it proved to be a subhepatic abscess, identical in situation and in character with Case 1. The patient recovered.

Case 3.—A man, aged 38, resident in London for ten years, who had at one time served in the army in Malta, but have since never left the British Isles. The clinical evidence all pointed to the presence of pus in the gall-bladder, but when the abdomen was opened, an abscess reaching from the anterior to the posterior border of the liver parallel and to the right of the gall-bladder was found. The abscess was opened and drained by an opening both in front and behind near the angles of the ribs. The patient recovered.

Case 4. *The Effect of Sterile Pus in the Cavity of the Abdomen.*—A sailor, aged 35, recently in the Royal Navy, had to leave his ship with all the signs and symptoms of liver abscess. At first he refused to be operated upon, and it was not until the severity of the illness became alarming that he consented. On cutting down upon the swelling in the right hypochondrium an abscess was found on the under-surface of the liver; the wall of the abscess had attained adhesion to the peritoneum in the right lumbar region, and the pus extended as low and as far back as the upper end of the right kidney which was incorporated with the swelling. Moreover, the pus had burst into the cavity of the peritoneum. The contents of the abdomen from diaphragm to pelvis were covered over by a slimy, muco-purulent-looking fluid. There were no signs of peritonitis, no adhesions, no flocculent pus, nothing except this passive effusion of slimy, muco-purulent-looking fluid in great quantity. The pus from the abscess cavity and the semi-fluid material from the surface of the peritoneum were examined bacteriologicaliy, and both were pronounced sterile. This is, so far as I know, the first recorded case of the kind, and it is of special interest.

The treatment in this case consisted of free incisions in the abdomen in right and left lumbar regions, and in the middle line below the umbilicus, flushing the abdominal cavity with saline solution, and the insertion of large drainage tubes. The liver abscess was drained separately. The patient is now (June 11th, 1906) convalescent.

Case 5. — A man, aged 37, resident all his life in Britain, had signs and symptoms of abscess of the liver in 1904. The abscess was not operated upon, and the pus burst upwards through the lung. The expectoration of pus ceased, and the patient for a time was fairly well. After four months the local signs and symptoms returned, and again he went into hospital; no operation was performed, and again he seemed to recover, but without any expectoration of pus. He continued to have hepatic pain and fever at intervals until May, 1906, when I found him with increased temperature, an epigastric swelling, local pain, and general discomfort. After five days he came into hospital, by which time the swelling had disappeared, the temperature had fallen to normal, and the patient said that the day before he came into hospital he had passed at stool a large quantity of "the same material he had on a previous occasion coughed up." It was plain the abscess had burst into the bowel, the colon in all probability. So far as I can learn, this is the only instance of a hepatic abscess which has been known to burst in two directions, namely, upwards through the lung and subsequently downwards into the bowel.

When cut down upon, an abscess was found on the under-surface of the left half of the liver near the posterior border; the liver, stomach, and colon being adherent to the wall of the abscess. The treatment consisted in exposing the swelling, packing the wound, and at the end of a week opening and draining the cavity. The pus from this abscess was sterile—a peculiar and most unexpected condition, seeing that there had been a double source of possible contamination, namely, by way of the lung and by way of the bowel. The patient is still under treatment.

THE ANATOMY OF THE BITING FLIES OF THE GENERA *STOMOXYS* AND *GLOSSINA*.

By Lieut.-Colonel G. M. Giles, I.M.S. (Rtd.).

(*Continued from p.* 173.)

The œsophagus, after its commencement in the pharynx is a rather delicate tube. As seen in fig. 24, A, it is lined with an extremely delicate membrane, which is probably smooth in the fresh state, but is much wrinkled as seen in a transverse section on account of the shrinking action of the reagents employed on the softer tissues. In some of the folds thus produced there will always be found minute bodies which stain strongly with nuclear dyes and possibly are nuclear bodies. The main thickness of the walls of the tube is, however, formed of a ring of faintly granular material which shows fairly clearly a longitudinal striation, as seen in transverse section. These fibres are probably muscular. In the same sheath with these and lying always towards the lumen of the tube are some oval nuclei provided with a distinct nucleolus.

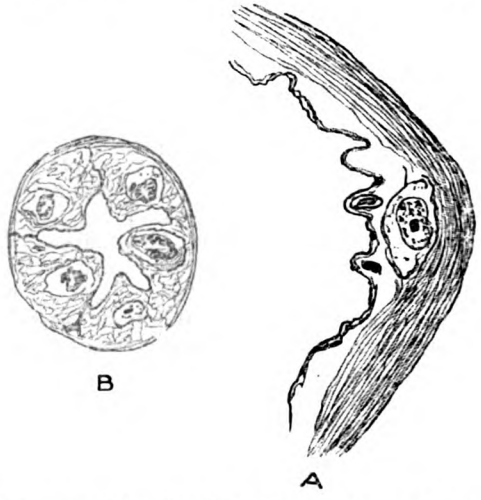

Fig. 24.—A, portion of wall of free œsophagus in transverse section: B, transverse section of the œsophagus as it passes through the nerve collar.

There are rarely more than two of these, usually almost opposite each other, in a fairly thin transverse section of the organ, and I believe them to be muscle nuclei. Outside these are some scattered cells of about the same size as these muscle nuclei, but they do not seem to be concerned in the structure of the tube, and are more probably lymph cells.

The narrow portion of the œsophagus, when it passes through the nerve collar, has a very different structure. The muscular and chitinous coats are both so thin as to be barely perceptible, and the place of the small nuclei, to be seen between the folds of the chitinous inner lining of the first part, seems to be taken by a continuous coat of large cells which have the appearance of epithelial elements. The lumen is here stellate in transverse section, and, on account of the size of the above-mentioned cells, extremely contracted.

The histology of the nerve centres does not differ from that of other diptera, a prominent character of which is the smallness of the component cells. In the layer of grey matter that surrounds the white commissural masses, two distinct forms of cells can be distinguished. In one of these, which one would be inclined to believe motor in function, the structure consists of multipolar cells, usually about the diameter of a human leucocyte. They have large nuclei, but still possess a considerable volume of protoplasm. Their prolongations give off fibres which occasionally can be traced for some distance. A good example of a ganglionic mass of this structure is to be found on the surface of the ventral nerve cord in the middle line.

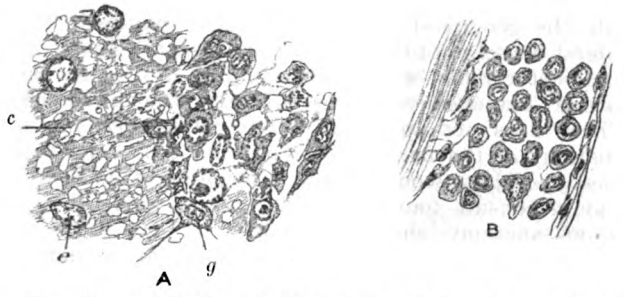

FIG. 25.—A, Portion of the ventral commissure and of the motor median ganglionic mass in that situation; *c*, commissural structure; *g*, motor ganglion cells; *e*, elements embedded among the commissural fibres. B, Cortical layer of anterior surface cerebral lobe.

The greater part of the sides of the cerebral masses is occupied by the ganglia of the compound eyes, the retinulæ of which are continuous with the cerebral mass, but this has been too frequently described to render desirable any further description here. An account, running to some 70 pages, will be found in Lowne's work already quoted, commencing p. 515.

On the anterior surface of the brain, however, between the compound eyes, is a ganglionic layer which is probably sensory in function. The component cells of this are quite different from those of the presumed motor areas, the cells being smaller (about the diameter of a human red blood corpuscle) and apparently for the most part quite without prolongations, though a few scattered cells of larger size show an irregular outline, which suggests the existence of these. There are four or five rows of these, and between them and the white matter lies a row of very small and distinctly multipolar cells. The outer surface of the brain is bounded by a membrane formed of closely adherent spindle-shaped cells, with large oval nuclei. In other places the thickness of the ganglionic masses may be as much as 20 or 30 rows of cells deep. In using the word "row" it is not implied that the cells are arranged in regular strata, as their disposition is quite irregular, but refers merely to the number of cells which may be counted in the width of a section. In specimens stained with borax carmine, a number of black pigment granules will be seen in these cells, and impart to them a very characteristic appearance, which is useful in recognising similar ganglion cells, in other situations than the brain, as, for instance, in the subcuticular tissue, beneath the sense organs of the antenna, but in staining with hæmatin and most of the aniline dyes, they cease to be distinguishable, on account of similarity of colouration with other deeply stained granules. Between the various bands of fibres of the white matter, may be found a number of ganglionic masses, composed of cells of each of the above descriptions, though the motor type predominate. Lastly, scattered between the fibres are a number of large clells or nuclei (*e*), presenting a large, clear, central area, and round their periphery a number of deeply staining granules, but these are probably not nervous structures at all, but of a trophic function.

In Mr. Austen's monograph of *Glossina*, mention is made (p. 63) of a sense organ placed near the base of the third joint of the antenna, but without any detailed description of its structure. In the corresponding position in the antenna of *Stomoxys* a similar organ is to be found, which, though I have made no examination of it in the former genus, has probably a similar structure. Judging from Lowne's figures, this organ is represented also in the blow-fly, but differs somewhat in details of structure.

In *Stomoxys* the aperture of the organ is oval and is hidden by closely set, long, flexible hairs. This slit opens into a sausage-shaped saccule, within which is a T-shaped projection which springs rather from the anterior side of the saccule, the stem being short and the top of the letter long and generally conforming to the outline of the cavity, so that it appears as an isolated piece in transverse sections that pass elsewhere than in the plane of the stem. The whole of this cavity is lined with peculiar stiff hairs, the bases of which are short and conical, while they end in a long bristle. These chitinous structures overlie a layer of ganglionic cells, from each of which a fibre runs to a hair, while proximally each ganglion cell receives a fibre from a ganglionic enlargement of the antennal nerve, which fills up the greater part of the cavity of the second antennal joint. The function of the organ is probably that of hearing. In addition to the saccule the whole surface of the organ is covered with sensory hairs, each of which has a similar nerve supply, and in the neighbourhood of the sacule are a number of peculiar sense organs of a quite different character. A number of these are to be found amongst the bases of the long soft hairs that guard the mouth of the saccule, while many others of considerably larger size are contained in a porous plate on the outer face of the antenna which is comparatively free from hairs. Though varying a good deal in size, even in the porous plate, they all have essentially the same structure, and consist of an ovoid crypt, communicating by means of a pore with the exterior, and springing from the base of which is

a club-shaped body which fills most of the interior of the crypt. From the club-shaped end of this body springs a soft conical hair, the fine termination of which projects into the pore. Two rows of very large organs of this sort are also to be found on the posterior face of the antenna. The nervous supply of these peculiar structures is exactly similar to that of the other hairs. They are believed to be olfactory organs, but in view of their graduated size it would be open to any one to suggest that they are chordotonal

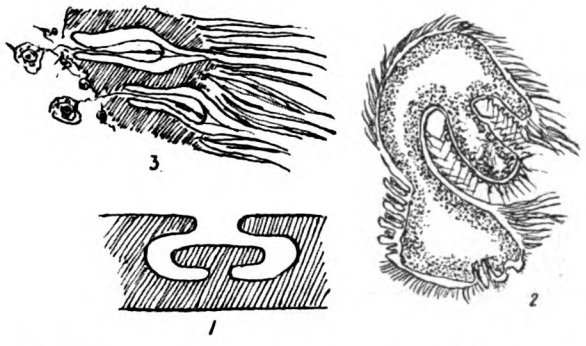

FIG. 26.—The sense organs of the antenna. (1) Diagrammatic longitudinal section; (2) transverse section, × 250 diams.; (3) vertical section of position of outer wall of antenna, × 700 diams.

organs. That certain insects lose the sense of smell, when deprived of their antennæ, has been fairly proved by Lubbock and others, but as to which of the various sense organs found on the appendage may serve this or that function must always remain a matter of pure conjecture.

The thorax in all diptera is little else than a solid mass of muscle. If we snip off with sharp scissors, the legs, with a little of the ventral wall of the thorax, the ends of a number of vertical bundles are seen cut across. These are the coxal muscles of the three pairs of legs, and if these be separated in the middle line there will be seen opposite the anterior legs a sausage-shaped mass of considerable size, the great thoracic ganglion. Clearing this away and just under its anterior end will be seen a nodule of the size of a small pin's head, and closer inspection will show that there extends backwards from it a glistening tube which is most characteristically marked with closely placed mammilations. This is the mid-gut, and lying on it will be seen three delicate tubules, the middle and most delicate of which is the crop duct and those at the sides the now glandular salivary glands. The mid-gut can be traced forwards beyond the nodule, and with sufficient care can be shown to be continuous with the œsophagus, as it escapes from the nerve collar. The nodule is placed at the junction of the stomodæum with the mid-gut, and is known as the proventriculus, a very peculiar organ, which will be described in detail further on. If these parts be removed it will be seen that all else is muscle. Pressing apart the masses in the middle line, layer after layer (four in all) of longitudinal muscle can be clearly seen, filling up the greater part of the space. Further out there are numerous more or less obliquely vertical bundles. The whole constitute the muscles of flight; for the wing roots are not acted on directly by the muscles, as is the case with the ventral appendages, but in a very indirect manner by their action in producing an alteration in the form of the chitinous exoskeleton of the thorax, and thereby actuating a complicated series of sclerites which are connected with the wing roots. Any attempt to describe these muscles and their action here is, however, clearly out of place; and indeed, though much has been written on the subject it is very doubtful if any one has yet solved the problem of their mechanics.

The thoracic ganglion is mainly contained in the mesothorax just above its sternum, but the oval ends extend before and behind into the contiguous portions of the pro- and meta-thorax. Sections show that there are three principal ganglionic masses: a median commissural ganglion, which is divided into three parts, and lateral ganglia which are so continuous as to leave but little indication of the original separation into the ganglia of the three thoracic somites. The lateral branches of the ganglion have separate sensory and motor roots, and ends behind in a median and lateral branches which extend into the abdomen. There does not appear to be any difference in the anatomy of the nervous system from those of other flies, and those who desire a description of its details should consult some standard work on general dipterous anatomy, such as Lowne.

The proventriculus is a very peculiar structure which forms a sort of three-way junction between the œsophagus, crop duct, and mid-gut, and is situated in the prothorax, lying upon the cephalo-thoracic nerve cord and the front of the thoracic ganglion. Apart from certain differences of moulding, it is essentially the same in all Muscidæ, so

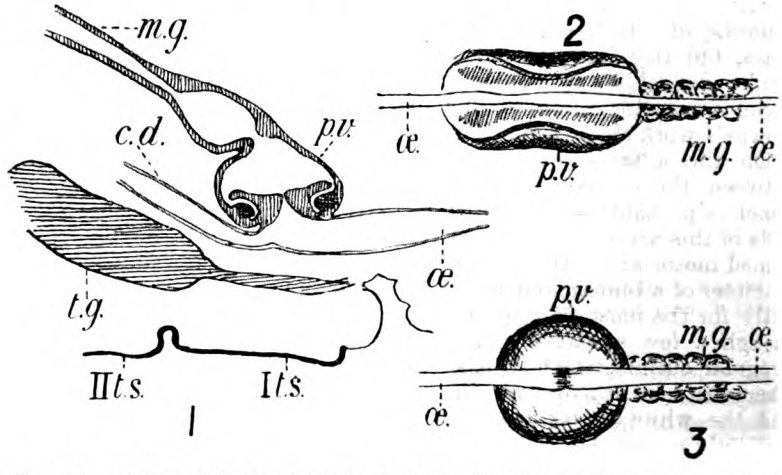

FIG. 27.—(1) Camera lucida drawing of a sagittal section of the proventriculus of Stomoxys and its connections, × 50 diams.; (2) and (3) freehand drawings of the proventriculi of *Glossina palpalis* and *Stomoxys calcitrans* respectively viewed from below; *Its*, *IIts*, first and second sternal sclerites; *cd*, crop duct; *mg*, mid-gut; *œ*, œsophagus; *pv*, proventriculus; *tg*, thoracic ganglion.

that our description of the organ will, with a few added words as to differences, serve equally well for *Stomoxys* and *Glossina*. The body of the organ consists of a fairly thick-walled bulb, from the dorsal surface of which springs the mid-gut, while the crop duct and œsophagus are connected with the ventral.

As will be seen from an inspection of fig. 1, the organ in *Stomoxys* closely resembles a retort, the beak of which is formed by the mid-gut.

The œsophagus and crop duct, which really form a continuous tube, give one the impression of entering the under-surface separately, as seen in dissecting, but do not really do so, the illusion being produced by the actually continuous tube being tucked up into the funnel-shaped aperture in the lower surface of the proventriculus.

In *Glossina* the junction is T-shaped, and there is a distinct vertical duct which runs up from the upper surface of the junction between the œsophagus and crop duct, so that, even to the dissector, the continuity of the latter is quite obvious. In both genera, however, the vertical diverticulum enters the proventriculus by piercing the centre of a very peculiar structure, which has exactly the form of a bone button, the sewing which would attach such a button to the cloth being represented by a stout peduncle, through which the vertical diverticulum passes to enter the cavity of the proventriculus. Concealed beneath the margin of the button is an annular thickening of the floor of the cavity, which is formed of peculiar clubbed cylindrical epithelial cells.

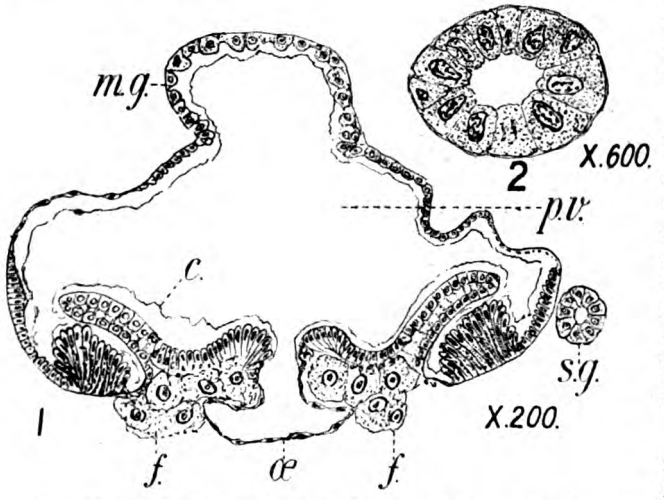

FIG. 28.—(1) Transverse section of proventriculus, × 200 diams; (2) transverse section of salivary glands; *c*, chitinous lining membrane; *f*, fat body; *mg*, mid-gut; *œ*, œsophagus; *pv*, cavity of proventriculus; *sg*, salivary gland.

A ring of somewhat similar structure, in the middle of the upper surface of the button, surrounds the almost punctiform opening of the vertical diverticulum. The lining, indeed, of this curious structure presents a sort of epitome of the various types of epithelial cell. Both surfaces of the remainder of the button are paved with cubical cells; outside the thickening beneath it the floor of the cavity is composed first of cubical and then of columnar cells; the lower part of the vault is composed of elements of the squamous form, and these change again to the cubical type, which, in its turn, gradually changes to the much larger irregular glandular type of cell which lines the commencement of the mid-gut.

The œsophagus and crop duct may be taken as chitinous stomodæal tubes, and it is a curious circumstance that this chitinous lining is continued through the vertical diverticulum into the proventriculus, and lines its entire cavity, though there appears to be no organic connection between this lining and the epithelial coat already described.

Though extremely delicate the structure is perfectly definite and continuous; and though fluids doubtless easily osmose through it, it seems rather difficult to understand how the products of the epithelial waste are disposed of. Taking the structure as a whole, it is difficult to resist the idea that it must, in some way, have a valvular function, though it is difficult to say how. The button is a solid mass of epithelia, and a most careful search through many series of sections has entirely failed to demonstrate any muscular components. The only way in which the puncture can be imagined to be closed by the structures as they stand is that the ring of club-shaped epithelia, beneath the button, if secreting actively, might swell and so cup the button more deeply, and that any such alteration of form would certainly tend to close the puncture. Weismann believes it to be glandular, and Lowne regards it as a gizzard, and there can be no doubt, as the latter points out, that it is homologous with the gizzard of manducatory insects, but it is difficult to see what a blood-sucking insect wants with such an apparatus, and as a matter of fact, but little changed red corpuscles of the victim are constantly to be found on the mid-gut.

In *Stomoxys* the proventriculus opens into the mid-gut by a very narrow opening, followed immediately by a bulb-like dilatation; after which the gut contracts to a uniform diameter for the rest of its passage through the thorax, but no such dilatation appears to exist in *Glossina*. In this genus, too, the button is oval instead of circular, and the entire organ is oblong with rounded corners and very slightly contracted in the middle. In addition to this (fig 27, 2), whereas in *Stomoxys* the organ is convex below in all directions, in *Glossina* the sides are curled round to protect the œsophagus and crop duct, so that, seen from below, it has much the form of a Spanish priest's hat.

The salivary ducts, almost immediately after entering the thorax, change from minute chitinous tubes to large tubular glands, and run back below the œsophagus to the sides of the proventriculus, and then below the digestive tubes to the abdomen. They are 0·08 mm. in diameter, and are lined with a cubical secretory epithelium, the components of which assume a keystone form on account of the smallness of the lumen. They have large nuclei with prominent chromatin fibres, and show neither anything in the way of a basement membrane nor any chitinous lining (fig. 28, 2).

On the dorsal side of the digestive tube, and lying in absolute contact with it, is the aorta, but the peculiarities of its structure will be better described in connection with the abdominal dorsal vessel.

(To be continued.)

THE PURU OF THE MALAY PENINSULA.

By T. D. GIMLETTE, M.D.

(*Continued from page* 175.)

CASE 3. *Puru in a Malay Adult.* — Mehlimah, female, Kelantan Malay, aged 47, married, twelve children, was first seen on April 14th, 1905, at Lubok Kawah in Kelantan. The patient states she has been ill for about a year, and has been inoculated with "puru mata kerbau" by her youngest child, aged about 2, who, with his sister, aged about 6, is now recovering from the disease. She says that all her children have had puru, but up till the present time she herself had not had it. Her husband suffered from it in boyhood; a married sister, however, has not yet had puru.

The patient looks ill. The eruption is sparse. She is crippled and complains of great pain in the hands and feet, and in the wrist, elbow and knee-joints. The joints are swollen and very tender. She is kept awake at night by the pains, and has been confined to the house for many months. She is still suckling the youngest child. On the left breast there is a flattened puru tubercle covered with a dark dry scab. There are some similar lesions on the abdomen about the level of the umbilicus, where the child would naturally be held in nursing. The shin-bones are much swollen and tender, as well as the phalangeal joints. The scar of the "puru ibu" in this case was on the right shin. The ibu sore had healed before the decline of the other sores, which, with the exception of those on the body, had mostly come out on the neck. This patient was given a mixture containing iodide of potash, 10 grains, night and morning, and an ointment composed of ung. hydrarg. 1 drachm, and zinc ointment to 1 ounce. She was greatly benefited by it, and by the end of April was free from pain and able to walk alone. At the end of May the sores had all healed.

CASE 4. *Puru in a Sikh.*—Pak Singh, a Sikh, of no occupation, aged 39, was admitted to the General Hospital at Kuala Lipis, Pahang, on February 2nd, 1900. He had been ill for a few days, and was supposed to be recovering from chicken-pox. He was removed to an isolation ward, where the eruption developed into one which was generally recognised as puru. The patient gave a definite history of primary syphilis, and was not discharged until April, and then only partly cured, although treated with mercury as well as iodide of potash during the whole of March.

This case appears to be analogous with the clinical case of the sea dyak given by Dr. Barker in his report from Sarawak.

THE PATHOLOGY OF PURU.

There is little in the pathology of puru which has not already been described under the heading of frambœsia or yaws.

The disease being seldom fatal, it is impossible to record the result of any *post-mortem* appearances, more especially because *post-mortem* examinations are almost prohibitive among Malays owing to religious custom and strong racial prejudice.

Microscopical Appearances of Puru Tubercles.—Some of the growths which were removed from the chin and back of Case 2 were sent to the Institute for Medical Research, Federated Malay States, and were, by the courtesy of the Government, examined by Dr. C. W. Daniels, the Director of the Institute. His report is as follows:—

"*Tubercle from Back.*—Nodule mainly composed of a round-celled growth in the tissue, covered almost completely by altered epithelium. The growth is not one mass, but is formed of a series of nodules of irregular size and shape loosely connected by fibrous tissue.

"On tracing the epithelial layer from the normal skin at the edge of the nodule we find that over the tumour it is more irregular in thickness and that the papillary processes are larger and very irregular. All the layers are altered. There is no properly formed keratinous layer and none of the intermediate cells in process of keratinisation. The epithelial cells over the tumour are swollen, stain irregularly, and are often vacuolated.

"They are not arranged in definite layers and the palisade arrangement of the deepest layer is poorly marked.

"The growth itself is composed of round cells with scanty protoplasm. The cells and nuclei stain well with basic stains. Mitosis is common and there are no areas of necrosis, caseation, or suppuration. The cells vary a little in size and occasionally much larger cells with single nuclei are seen. In the depth of the growth there is some thickening of the fibrous stroma. The growth is supplied with blood-vessels.

"*Tubercle from the Chin.*—This specimen is from a more hairy part and hair follicles extend through the growth. It differs from the other specimen in that the growth is less abundant and the fibrous stroma more so and that the hair follicles extend through the depth.

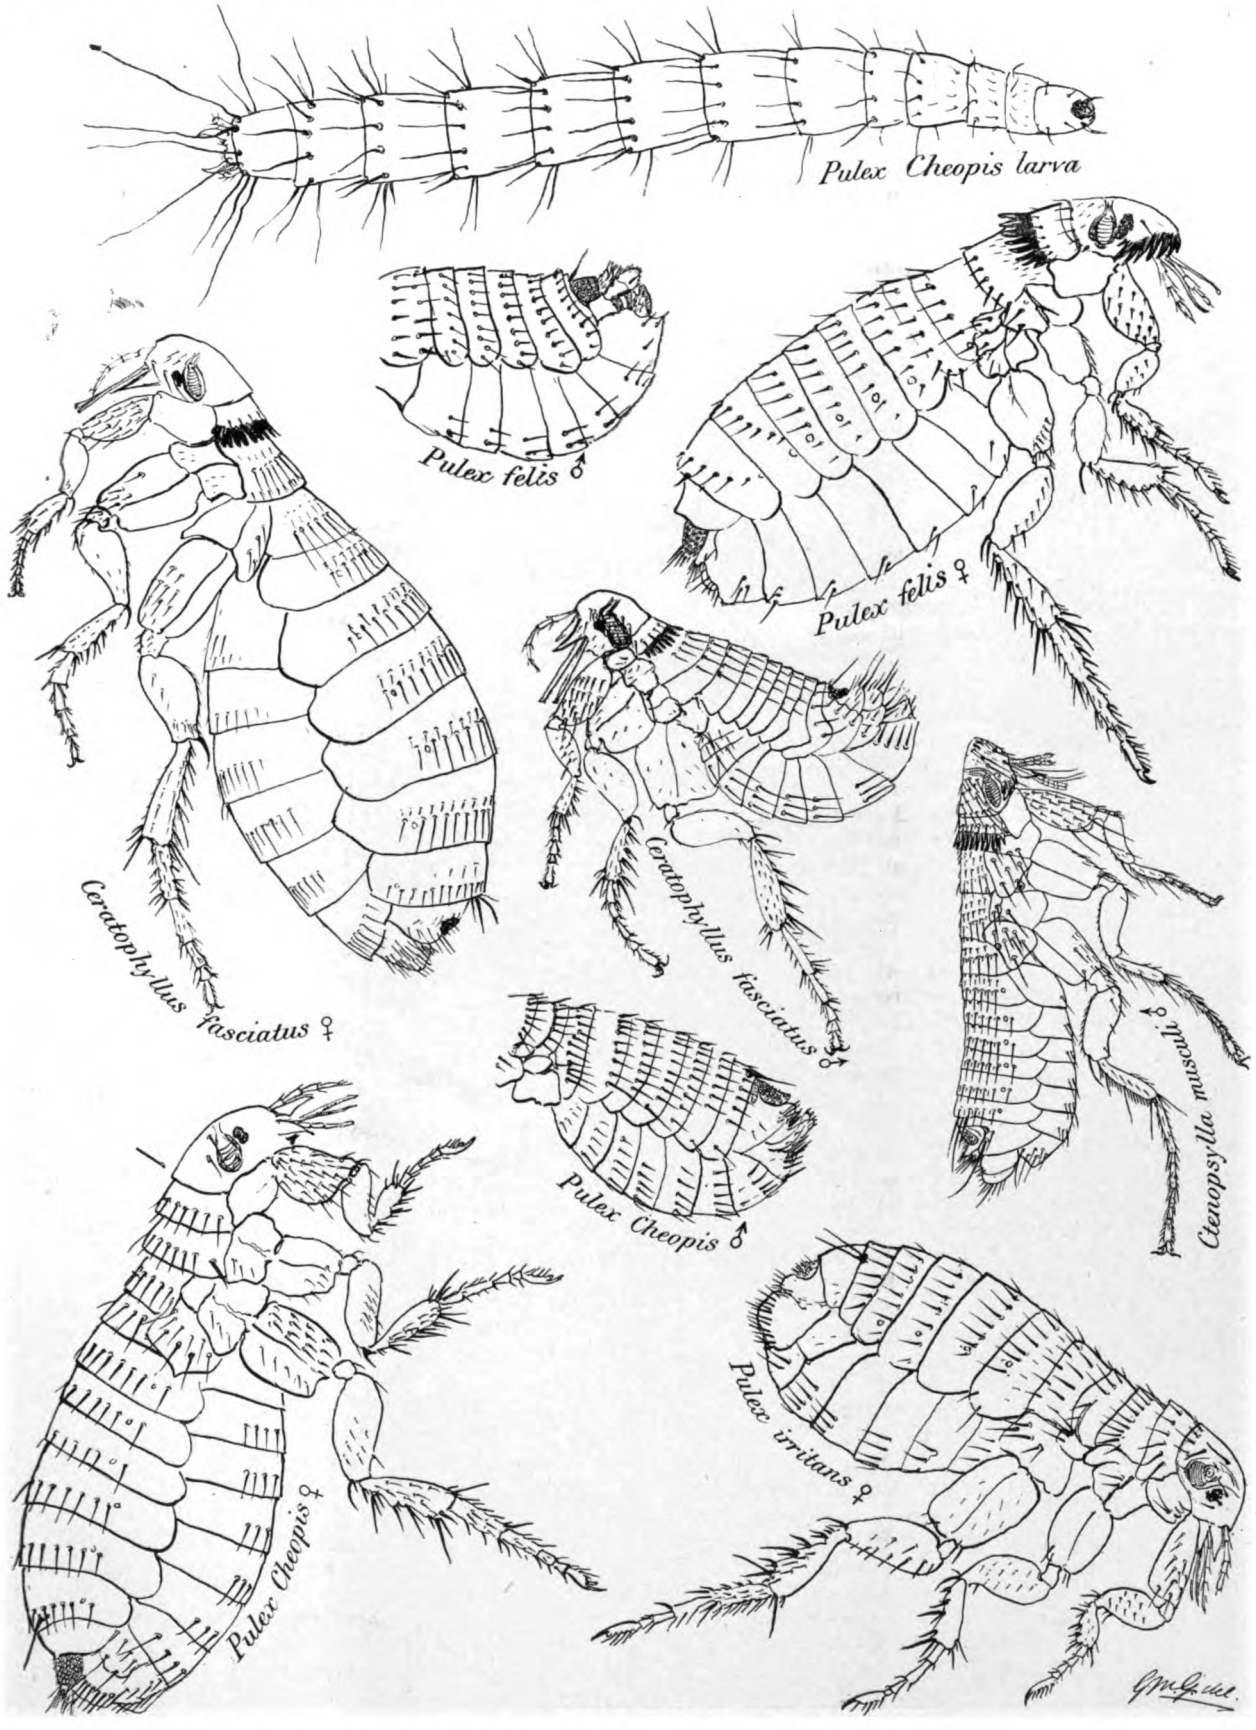
"No micro-organisms were found in the deeper parts of the sections of the growths."

This description agrees with the most recently published account of the microscopical appearances of frambœsia or yaws tubercles [20]. It is important to note that no congener of the *Spirochæte pallida* was found. The original sections are sent with this paper.

THE TREATMENT OF PURU.

Malays have given much attention to the treatment of puru, both with drugs derived from their own flora and by the use of a few imported medicines, but their efforts, which are mainly empirical, have not proved very successful in every-day practice.

In the hope that a definite therapeutic preparation might be made out of one or other of their local products, I recently sent some notes to the Therapeutical Society of London, on some of the methods employed by Kelantan Malays in the treatment of puru. Botanical specimens of most of the plants referred to were sent to England with the paper. They were all obtained in Kelantan, most of them from a hamlet—Kampong Kutan—near Kota Bharu, the capital. These original notes, with additions, are now embodied in the present essay.



Outline figures of fleas possibly concerned in the transmission of plague.

Native Therapeutics.—In the earliest stage of the disease the only native form of treatment employed for the relief of the prodromal fever and muscular pain is the superstitious Malay practice of "menjampi," or charming by incantations.

The medicine for the first stage of puru is said by native Malay doctors to be the leaf of the merbor (?), plant and those of the jenera (?) rotan jenerang (*Dæmonorops draco* [L. Palmæe], the dragon's blood). These leaves are chewed up and spat on to the swelling or ibu.

It is generally held by Malays, however, that active treatment is of no avail until the full development of one or more puru sores has been attained. The sore which is often watched with the object of timing the commencement of treatment is the "puru ibu," or mother sore. When this so-called parent sore is developed, their most valued remedy is the external application of a latex or kind of gum which is called "geta hagu" in Kelantan, or "getah jintan" in Pahang. This is obtained from a climbing jungle creeper known in Kelantan as "akar agu" ("akar," a root, the generic name for scandent or creeping plants) and is very like *Hunteria roxburghiana*, though uncommon. It is prized by Malays, especially a red variety, and, like many other of their medicinal plants, is protected and cultivated. The latex is obtained by cutting the live stem and mixing it with water to allow for its inspissation, and it may be bought in this form in the native market at Kota Bharu in Kelantan. The remedy is smeared day by day on the sores of the general eruption. So far as my experience in Kelantan goes, "getah agu" causes the sores of puru to shrink and is of value as a local application.

Another latex which is valued is collected from a jungle creeper called "akar gam" (*Willoughbeia firma*); in this case the remedy is obtained by incising the fresh fruit or the stem. It is generally known under the name of "buah gam" or "gehan" ("buah," a fruit), and is commonly applied to the sores of puru in the same way as "getah agu." In some cases in which the sores are chronic and do not respond to treatment the fruit is gathered, dried, then roasted and powdered, being finally made into a paste with a little water for local application. In other cases of chronic and recurring sores, the ashes obtained by burning the stem of "rotan sega badak" (*Calamus orantus*) are used. "Rotan," in Malay, is a generic name for rattans of the genera *Calamus* and *Dæmonorops*.

Another local Malay remedy is well known under the name of "terosi," sulphate of copper. In the general treatment of puru, "terosi" is reduced to fine powder, and then mixed with palm oil or with a latex called "getah pulai," which is obtained by cutting the stem of the young pulai tree (*Alstonia macrophylla*). External applications of this kind containing "terosi" cause a great deal of pain, prevent sleep, and on this account are not often used, rarely if ever being employed in the early stages of puru. With the object of preventing pain these applications are sometimes prepared by first burning the "terosi" in a slow fire until it is blackened, then pulverising and mixing it into a paste with either cocoanut oil or the juice of the common lime fruit called "limau nipis" (*Citrus acida*).

The most important of all the Malay drugs for sale in the Kota Bharu market is "tuba tikus," which, like terosi, is imported by way of Singapore. "Tuba tikus" is pure arsenious acid or white arsenic, generally seen in rather odd forms which seem to be due to its having been collected from the flues of some dyeing works. The name appears to be used idiomatically by Malays; "tuba," is the name of a jungle plant, the root of which possesses certain stupefying properties; "tikus" signifies a rat. It is used externally in the treatment of puru, either by itself in the form of a powder, or as an addition to various kinds of roughly made "pastes" which are prepared from certain native plants. These vegetable "pastes" are freshly made as occasion demands; in one instance by grinding down with a little water the root of a wild red vine, called in Malay "puchok merah" ("merah," red), a plant which is identical with *Leea rubra*, and in another case by treating in the same way the root of a low shrub called "chekor manis" (*Sauropus albicans*); "manis" is the Malay for sweet, or light in reference to some colours.

"Taba tikus" is used as a poison by criminals, and is not administered internally as a medicine by Malays. It is the "berangan puteh" of Java.

The sulphurets orpiment and realgar are also used in puru, but all the external applications containing arsenic, being caustic, are much disliked on on account of the pain which they occasion. "Tuba tikus," like "terosi," may be burnt and applied in the same way, either with or without oil.

"Mali puchok merah" is given by the mouth for puru, as well as being used externally, and among other internal remedies are "melor hutan," a wild jessamine (*Jasminum bifarium; Oleaceæ*) and the black variety of kemantu. This latter is a tree of Indian origin (*Clausena excavata*). It is called "pokoh kemantu hitam," or the black kemantu tree, "pokoh" meaning a tree, and "hitam" black. There are other varieties of this tree which are not used in medicine. "Akar jela batu" is also administered internally for puru; but there is no fixed dose. In each case the roots of these plants are ground down on a "batu asah" (a stone on which medicines are pounded or ground down) and then infused in cold water. Occasionally a mixed infusion is used in puru of kemantu hitam and "tuko takal" (*Baccaurea wallichii*; *Euphoribiaceæ*), a jungle tree which is fairly common.

The only treatment of the disease by Malays when it affects the joints is by the constant application of "ayer tawar," or plain water over which certain charms have been said.

In Kelantan sovereign remedies are common. A typical native prescription is as follows: Take the knee-cap of a tiger, the bones of a duyong (the dugong), the bones of a goose, the bones and horns of a Kambing gurun (a very rare wild goat, *Nemorrhædus bubalinus*), the horns of a rusa, a wild deer (*Cervus unicolor*), while still soft (lembong); add belirong bang (sulphate of arsenic), and chendana janggi (red sandal-wood), and mempus harimau (a kind of wood). Grind these ingredients down with some boiling rice water (ayer dideh), take a small amount of ashes

from the hearth, mix, and administer the draught by the mouth.

Various applications are made for puru of the foot. The following method of treatment known as "tanak puru" ("tanak," to cook) is a favourite one with some Kelantan Malays. A small round hole about a foot in depth is made in the ground, and a slow fire is kindled at the bottom of it; half a cocoanut shell with a hole in it, or a suitable piece of bamboo, is then fitted over the red-hot embers. On the top of this improvised screen the affected foot is rested in such a way as to expose the sore to the heat of the smouldering fire. Kemantu leaves are often put on the fire as well as those of "kedondong," a tree belonging to the genus *Canarium*; in addition to the leaves the bark of the latter is sometimes burnt on the embers. Relief of pain is obtained after three or four lengthy exposures.

Lime, which is commonly used in betel chewing, is also a popular remedy for puru of the foot. It is mixed with oil or with the juice of "keladi puyoh," a common Malay ariod of the genus *Alocasia* (*Typhoaium roxburghii*), and plastered on to the sores. Stones may be heated and applied as hot as can be borne. The actual cautery in the shape of red-hot iron nail is occasionally used, and even excision is attempted by means of "parangs" or rough iron choppers which are usually used by natives in felling brushwood.

It is of general interest to note that the drugs used in puru are not used by Malays in their treatment of syphilis. The chief Malay drug used for syphilis is "pokoh restong" (*Malacuœ sp.*) which grows wild, but is often cultivated, and it is praised by natives as being a valuable medicinal product. The root is used, mostly in the form of a lotion, especially in cases of ulceration and destruction of the nose. This as well as "trong pipit puteh" (*Solanum indicum*) is also given internally for syphilis, but they are not employed in the treatment of puru. "Puteh," in Malay, literally means white, and the word "trong" is used to designate the plants of the *Solanaceœ*.

Hospital Treatment.—At the present time puru is rarely, if ever, treated in the isolation wards of the Malay peninsula. It is hardly necessary to dilate upon the importance of isolation in the case of a directly contagious disease of this nature. I think it may be assumed that some isolation of puru cases (although prophylactic treatment of this kind must always be difficult among Malays) may be eventually achieved in these hospitals.

Preparations applied locally of mercurial ointment will be found of great value in the treatment of the disease, especially in combination with zinc ointment. Sores which are healing during the decline of the disease are generally benefited by daily applications of tincture or liniment of iodine. Puru of the foot is often relieved by the application of pure carbolic acid or sulphate of copper. I have not found alkaline lotions of sodium bicarbonate to be of much benefit. Iodine of potash is generally of great value, especially during the stage of "senggai puru." It quickly relieves, as a rule, the rheumatic-like pains if given in doses from 5 to 10 grains (to adults) twice or thrice daily. Attention to general hygiene and cleanliness is nearly always indicated. The syrup of iodide of iron is often of great service in the treatment of puru during childhood.

Although my practical acquaintance with the disease is limited to the Malay peninsula, I would conclude that puru is identical with frambœsia or yaws, and I would plead that this tropical disease should at least rank as a nosological entity in the medical returns of British Malaya.

I am indebted to Mr. H. N. Ridley, F.L.S., Director of the Botanic Gardens, Singapore, for his kindness in classifying very many of the drugs, and to Mr. P. Burges, M.A., Government Analyst, Straits Settlements, for his examination of the mineral known as "tuba tikus," or ratsbane; also to Mr. R. W. Duff, Managing Director of the Duff Development Company, Limited, to Mr. H. W. Thomson, Assistant Adviser to His Highness the Rajah of Kelantan, and to Ungku Sayid Hussein, a member of the Kelantan nobility, for their cordial collaboration.

I must also thank Dr. C. W. Daniels, the Director of the Institute for Medical Research, Federated Malay States, for making the examination of the pathological tissues and for many kindly and valuable criticisms.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 „ „ 6/-;
200 „ „ 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 „ „ „ 11/-;
200 „ „ „ 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

Journal of Tropical Medicine

JUNE 15, 1906.

THE HYGIENE OF THE ALIMENTARY CANAL.

PROFESSOR METCHNIKOFF chose the subject of "The Hygiene of the Alimentary Canal," for his second Harben Lecture. The etiology of appendicitis formed a prominent part of the lecture, and Metchnikoff's opinion is that intestinal worms are the most frequent cause of the disease. He cited instances in which Trichocephali, Oxyures and Ascarides have been found in the appendix, and drew attention to the prevalence of appendicitis in families and persons subjected to identical domestic environment. It is not necessary for belief in this opinion that the worm be actually found in the appendix either at operation or at *post-mortem* examination, for, after having caused inflammation in the appendix, the parasites frequently leave the appendix and thus may not be found there at the time of the operation. There can, of course, be no doubt that an intestinal worm need not impair health in any way, just as many mosquitoes, fleas, and ticks may prick man and animals without causing anything more than a transitory and not painful itching. But, on the other hand, it is equally certain that the bites of intestinal worms may lead to just as much evil as the pricks of Arthropoda carrying pathogenic microbes.

In the appendix the parasite sets up a zone of inflammation accompanied by an effusion of white blood cells and the presence of different bacteria; the mucous membrane is attacked and the parasite (oxyuris or other worm) inoculates a microbe which produces a fatal infection. The *rôle* of the parasite is therefore similar to that of a flea which inoculates man with the plague bacillus. As an argument against this theory of the causation of appendicitis, it is asserted that the Chinese and certain other peoples never suffer from appendicitis, in spite of the frequency with which intestinal worms are found in them. It may, however, be stated (1) that *post-mortem* examinations are but rarely carried out in China, except in some few centres where European doctors practise; (2) that appendicitis is frequently a mild ailment, and European doctors are seldom called in; (3) the statement that appendicitis is so rare amongst Chinese requires confirmation.

The disinfection of the intestine Metchnikoff considers to be a simple matter, and can be produced by keeping a careful watch on our food and drink; both should at least be boiled before being consumed. He refutes the belief that boiled water is either tasteless or harmful, and contends that boiling is insufficient for sterilisation—there always remain spores of *Bacillus subtilis* and some others—but the ova of parasites and the pathogenic microbes will be destroyed, almost without exception.

Among fruits, strawberries are chiefly condemned as parasite introducers, from the fact that they touch the ground or litter when growing. In connection with this legend the use of strawberries as a cure for sprue would require justification, seeing that the fruit comes in contact with an already damaged intestine. As an intestinal disinfectant lactic acid is recommended by Metchnikoff as the most efficient, and he states that—

"Among the useful bacteria the place of honour should be reserved to the lactic bacilli. They produce lactic acid, and thus prevent the development of butyric and putrefactive ferments, which we should regard as some of our redoubtable enemies. It has been shown by an extensive series of experiments, which we cannot here treat of in detail, that certain lactic ferments easily accustom themselves to live in our intestines, and thus produce a beneficial influence. They prevent putrefaction, and thus diminish the excretion of sulphonic acid esters. These same ferments help to regulate the functions of our intestine and kidneys, rendering valuable service to the entire body.

"One can take such carefully selected lactic ferments either in milk that has become acid under their influence or in the form of a powder or compressed 'tabloids.' Dr. Tissier employs them in the treatment of the various intestinal troubles occurring at any age. To this end he advises the use of cultures of lactic microbes made in lactose peptone water.

"As putrefaction in the alimentary canal represents one of the causes of the general wear and tear of the human body, it was only natural to suggest the method that I have just referred to as a means of combating it. This method may now be summed up in a few words. It consists in the consumption of foodstuffs not contaminated with microbes or entozoa, and in the introduction into our alimentary canal of an artificially cultivated bacterial flora, foremost among which are the lactic acid microbes."

HOW TO RECOGNISE THE SPECIES OF PULEX POSSIBLY CONCERNED IN THE TRANSMISSION OF PLAGUE.

THE theory that fleas are concerned in the transmission of plague is one of some standing, but was for a considerable period generally discredited, as it seemed that laboratory experiments failed to confirm its probability.

Of late the theory has, however, come once more to the front, owing largely to the able advocacy of Captain W. Glen Liston, I.M.S., who contributed to the Bombay Natural History Society a paper on the subject, read on November 24th, 1904. A revised copy of this paper appeared in this Journal in the issue of February, 1905, p. 43, and an earlier note on the fleas of rats, contributed by Dr. Tidswell, may be found in the volume for 1903, p. 232.

It is not our purpose to enter into any detailed description of the various species that may possibly be concerned in the transmission of plague from the rat to man, but as neither of these papers was illustrated, and no easily recognisable figures can be referred to as readily accessible, it is thought that it may be of service to our readers to furnish them with reliable outlines of the five species that are most likely to be met with in the course of any investigation of the subject. The material from which the drawings were made consists of a number of slides presented to the writer by Captain Glen Liston, and partly of some rat-fleas collected by himself in Plymouth.

All are mounted as microscopic objects in balsam on ordinary slides, and hence are probably a good deal more compressed than the living insects would be, or than is the case in specimens preserved in spirit. The depth of the drawings from dorsum to venter is therefore, probably, in all cases more or less exaggerated. The various specimens were most kindly identified by the Hon. Mr. Charles Rothschild, the well-known authority on the group, to whom the writer desires to express his most grateful thanks for his pains in this respect, as well as for his help in indicating the points that should be most emphasised in preparing outline figures of fleas, and for the loan of his unique specimen of the larva of *Pulex cheopis*, the species which is indicated by Captain Liston as the most probable culprit in the matter.

The fleas are a small group of parasitic insects, the *Aphaniptera*, which are generally regarded as a sub-order of the Diptera, though it cannot be said that the relationship is a very obvious one, as, not only are the wings represented only by small scales on the meso- and meta-thorax, placed just above the coxæ, but the hinder pair are usually the larger, and in no way resemble the halteres of the Diptera. Added to this, the mouth-parts are very different, notably, in possessing, in addition to the palpi, a second pair of jointed appendages.

Although no monograph of the *Pulicidæ* appears to have been as yet attempted, the total number of species must be considerable, as most genera of mammals and birds appear to have their own fleas, which are but rarely found on alien hosts. This, however, appears to be rather a matter of preference than of necessity, as, if pressed by hunger, fleas will attack almost any species, and as they always quickly desert their host after the death of the latter, other animals and human beings are, under the circumstances, very apt to be attacked by species that ordinarily neglect them. The significance of this trait of their habits in relation to the transmission of plague is too obvious to need further comment.

On this account, not only may the fleas of cats, rats, and even birds be found on men, but the fleas of the latter may be met with on rats, and of course the fleas of mice and other rodents find a comparatively congenial home.

For our purposes, however, there are five species whose ready recognition is like, ere long, to become a matter of vital importance to the medical practitioner. These are : *Pulex irritans*, usually harbouring on man ; *Pulex felis* (often referred to as *P. serraticeps*), commonly harboured by dogs and cats, but quite commonly met with on the human subject, as well as on rats, squirrels, and a variety of other animals ; *Pulex cheopis*, the common rat-flea in India, which, according to Captain Liston, appears to have a preference for *Mus rattus ; Ceratophyllus fasciatus*, common on rats in all parts of the world, and showing, according to Liston, a preference for *Mus decumanus* ; and *Ctenopsylla musculi*, normally harbouring on the mouse. In distinguishing between the above, the following points need alone be noticed :—

(1) The presence or absence of eyes. These organs are very rudimentary in all fleas, the compound eyes of the majority of insects being absent in the entire suborder. In *Pulex*, and allied genera, simple eyes allied to those of the young nematocerous larva occupy the position of the usual facetted eyes, but they are always small, and can hardly be capable of anything more than the bare appreciation of light. It is sometimes rather difficult to determine whether a species be blind or otherwise, as a pigmentary mark sometimes occupies the position of the eye, and may, of course, even really represent it, as the eye in its most rudimentary form is nothing more than a patch of pigment. *Ctenopsylla musculi*, the only blind species on our list, is, however, fairly obviously eyeless, and so can easily be distinguished from the rest.

The second point requiring particular notice is the presence or absence of serrated edges to certain sclerites, notably the inferior border of those forming the sides of the head, and the posterior border of the tergum of the prothorax. In this latter position they have the appearance of a spiked collar. Mr. Rothschild has recently described a flea possessing a mesothoracic collar of this sort, but this need not concern us here. Lastly, the posterior borders of some of the abdominal terga may show a tendency to this form of armament, the anterior segments of one of our species, *Ctenopsylla musculi*, possessing from one to three teeth on either side, but these are not easily made out in specimens mounted in balsam.

Fleas of the same species vary so widely in size that this character is practically valueless for purposes of identification.

These points being duly noted, our five species may be tabulated as below :—

I.—Species possessing obvious eyes.

(*a*) With both the inferior border of the head and the hind border of the prothorax serrated.

(1) *Pulex felis.*—Eight serrations to lower border of head, the hindmost much smaller than the rest. Prothorax with eight serrations on either side. Tarsal claws of moderate size, but stout.

(*b*) Lower border of head unarmed but prothorax serrated.

(2) *Ceratophyllus fasciatus.* — Prothoracic collar with ten serrations on either side. Tarsal claws small and delicate. The profile of the head curves down much more sharply to the vertical than in preceding or following species.

(*c*) Species with neither inferior border of the head nor the prothorax serrated.

(3) *Pulex cheopis.*—Tarsal claws short and delicate, antipygideal bristles long.

(4) *Pulex irritans.*—Tarsal claws long and scythe-like, antipygideal bristles short.

II.—Blind species.

(*a*) With the inferior border of the head and the prothorax alike serrated.

(5) *Ctenopsylla musculi.*—Inferior border of head with 4, and posterior border of prothorax with 11 serrations. Tarsal claws small and delicate. Profile of head sloping markedly backward, after it turns downward, producing an outline like that of the head of "Ally Sloper" of the comic papers.

We could have wished to complete the list with representations of the fleas harboured by monkeys, the familiar Indian verandah squirrel, and the Himalayian marmot, all of which animals are probably occasionally concerned in the spread of plague, but material is lacking. Perhaps some of our readers can supply us with the desired specimens, which should be sent, preferably, preserved in spirit.

Pulex cheopis is believed by Mr. Rothschild to be essentially peculiar to the hotter parts of the globe, but it is certain that it can maintain itself in temperate climates, as a specimen was taken by the writer on a rat caught in Plymouth. As a great naval arsenal, and considerable seaport, the town is in constant communication with all parts of the world, so that it is easy to understand its reaching there on a rat imported by some ship. The fact, however (which has already been published in an entomological periodical), is extremely significant of the dangers to which seaports are exposed. G. M. G.

R. KOCH ON TUBERCULOSIS.

In the Nobel Lecture, published in the *Lancet*, May 26th, 1906, Professor R. Koch drew attention to the infectious nature of tubercle, and to the necessity for notification of the disease. He stated that Bovine tuberculosis and human tuberculosis are different from one another, and in connection with the combating of tuberculosis it is only the tubercle bacilli emanating from human beings that have to be taken into account. Of tubercular persons, it is only those who suffer from laryngeal or pulmonary tuberculosis, and whose sputa contain bacilli that are dangerous to those around them in a noteworthy degree. This form of the disease was even called the "open" in contrast to the "closed" form, in which no tubercle bacilli emanate from the body in a dangerous form. In the open form of tuberculosis the patient is dangerous only when he is personally uncleanly, or becomes far advanced and more or less helpless in the disease.

The measures hitherto adopted for the arrest of tuberculosis are: notification, hospitals, sanatoria, and the instruction of the people as to the danger of tuberculosis. Of these the first and last are the most essential. "We must demand notification for tuberculosis" is Professor Koch's view, and all epidemiologists will agree. In a certain way notification is really taking place, as pulmonary phthisis is treated in many hospitals. The benefit of sanatoria is doubtful, and it is only in the early stage of tuberculosis that treatment in a sanatorium is of real use.

"PHILIPPINE JOURNAL OF SCIENCE," FEBRUARY, 1906.

INOCULATION AGAINST PLAGUE.

STRONG has inoculated man with attenuated *Bacillus pestis* with promising results. In all, 42 persons have been treated with one twenty-four-hour agar slant culture of the living bacillus, suspended in 1 cc. of 0·85 per cent. saline solution. The material was injected deeply into the deltoid muscle. Strong used a culture of attenuated strength, having obtained two attenuated cultures of the bacillus from Professor Kolle, and made use also of a three-year-old culture, started in Manila, still further reduced in strength, according to Otto's method.

After the injection the patient had slight pains at the seat of inoculation and a febrile state for a day or two, but no serious complications, either locally or constitutionally, resulted.

Of the several sera used as prophylatic or curative agencies in plague, the best known are: (1) Yersin, in 1894, prepared an anti-toxic serum by injecting the bacillus of plague into horses, and killed before use, by heating to a temperature of 136° F. (2) Haffkine, in 1897, used a pure culture of the bacillus in bouillon containing ghee, the bacilli being killed by exposure to a temperature of 158° F. for an hour. (3) Kolle and Otto, in 1902, inoculated guinea-pigs with attenuated living plague bacilli, and showed that these animals can be rendered immune to plague. (4) Strong, as stated above, has now adopted Kolle and Otto's method for human beings; the only special warning he gives is that every care must be taken in the preparation and attenuation of the virus.

YELLOW FEVER.

THE members of the French Commission for the study of yellow fever have issued their report. The conclusions are: (1) That the *Stegomyia fasciata* is the agent by which yellow fever is transmitted, thus confirming the observations of Reed, Carroll, Lazear,

and Agramonte. (2) The mosquito can only acquire power of infection by biting yellow fever patients during the first three days of the patient's illness. (3) Twelve days must elapse after the mosquito has imbibed the virus before its bite can infect human beings. (4) The infected mosquito retains its power of infecting man as long as it lives, namely, twenty to thirty days. (5) The *S. fasciata* requires human blood for the development of her eggs. (6) The first generation of the offspring of an infected mosquito seems capable of transmitting yellow fever fourteen days after reaching full development.

The micro-organism of yellow fever has not been isolated, but the following observations were made: (1) The organism does not exist in human blood after the fourth day of yellow fever. (2) It passes through the Chamberland filter F., but is retained by filter B. (3) The organism is destroyed by exposure to a temperature of 131° F. for five minutes. (4) The blood serum loses power of infection after exposure for forty-eight hours to air. (5) When defibrinated blood is protected from the air the serum retains its potency after five days but not after eight. (6) When dead infected *S. fasciatæ* are injested by non-infected *S. fasciatæ* infection results; but this infection only holds good for the first feeding.

As regards immunity, the members of the Commission conclude that: (1) An attack of yellow fever yields immunity usually permanent in this character; should a second attack occur it is of a mild type. (2) Serum kept at 131° F. for five minutes confers a relative immunity when injected into human beings. (3) The same is claimed for defibrinated blood kept under vaseline from air for eight days. (3) No race is naturally immune, but the mosquito seems attracted by certain skins.

Isolation of the patient and destruction of the *Stegomyia fasciata* seem to be the chief points indicated in warding off the spread of yellow fever.

The members of the Commission favour the idea that the micro-organism is of the nature of a spirillum.

Experimental Myiasis in Goats, with a Study of the Life Cycle of the Fly used in the Experiment and a List of Some Similar Noxious Diptera.[1]

By F. C. Wellman, M.D., Benguela, Angola, West Africa.

Abstract.

Dr. Wellman, in elucidation of this subject, employed a fly pronounced by Mr. E. E. Austen to be a species of *Sarcophaga*, near *regularis*, Wied. The animal experimented upon was a native goat of Angola.

The goat was chloroformed, placed under a mosquito net, and the nostrils of the goat painted with water in which pieces of putrid meat were soaked. Some 70 flies were then liberated beneath the mosquito net. The flies could be seen to settle upon the goat's nostrils. On the second day the goat appeared to be ill, it was killed on the third day, when the posterior nares and the frontal sinuses were found to be extensively eroded, swarming with maggots, and the air passages covered with a thin, glairy, foul-smelling pus. The experiment was tested by control animals. Dr. Wellman concludes that men and animals might be invaded by the fly in question under certain circumstances. A man sleeping in the open, especially if suffering from ozæna, would be liable to be attacked by the fly; any uncovered wound would also become affected.

A list of Diptera convicted of causing human myiasis is given by Dr. Wellman:—

Clyclorrapha — Schizophova — Muscidæ — Calyptratæ.

Oestridæ.

Gastrophitus. Horses and man.

Hypoderma. H. bovis, man. *H. diana*, deer and man.

Dermatobia. The larvæ of *D. cyaniventris* is the "Ver Macaque" of tropical America, and in man causes painful boils, occasionally attacking the eyes; also *Hypoderma bovis* reported by Scheube.

Sarcophagidæ.

Sarcophaga. S. carnaria, S. magnifica, and *S. rufi-cornis* occasionally deposit their larvæ in wounds of man (India). A species of this genus (*S. sp.* near *regularis*) is the fly used in the experiment detailed in this paper.

Sarcophila. Man and animals.

Auchmeromyia. A. luteola, in Angola, and another species (*A. depressa*), cause cutaneous myiasis in Natal.

Ochromyia. The larva of *O. anthropophaga* is the "Ver du Cayor," which in Senegal produces cutaneous inflammation and swelling.

Muscidæ.

Musca. Larvæ of *Musca sps.* occasionally are passed in fæces or found in wounds.

Calliphora. In intestines of man and animals.

Compsomyia. The larva of *C. macellaria* is the "Screw-worm" of tropical America.

Lucilia. L. sericata is the cause of "maggot" in sheep. The larvæ of several species of *Lucilia* have been detected in wounds and ulcers in man and animals.

Anthomyidæ.

Anthomyia. The larvæ of *A. canicularis* not seldom get into the stomach and intestines of man, through eating raw vegetables.

Hydrotæa. In the fæces of human beings.

Homalomyia. In the intestines of man, being passed alive in the fæces. Osler gives a case of infection by *H. scalaris* in Louisiana.

Hylemyia. In human excreta.

Correspondence.

To the Editors of the Journal of Tropical Medicine.

"ZAMBESI ULCER."

(Letter from Dr. F. C. Wellman.)

Sirs,—May I be permitted to remark in your columns on the criticism of the article by Mr. L. E. Ashley-Emile with the above title (this Journal, September 15th, 1905), which

FIG. 4.—To illustrate Case 2, showing the sores of puru.

FIG. 5.—A group of Malays at Dusun Nyor, in Kelantan, showing the prevalence of puru among the children of the village.

To illustrate article by T. D. GIMLETTE, M.D., "The Puru of the Malay Peninsula."

Bale & Danielsson, Ltd., London.

Mr. J. E. S. Old offers in your February 15th, 1906, number?

While I am not acquainted with the exact region described by Mr. Ashley-Emile, yet I have had some experience with skin diseases in the same latitude—from the Portuguese west coast to the head-waters of the Zambesi—and have often seen the common ulcers described by him (*vide* my "Notes from Angola," Note xviii., this Journal for December 1st, 1905, p. 344). I have also seen a number of cases of cutaneous myiasis, and am not inclined to regard the occasional presence of dipterous larvæ in ulcers in the light of an etiological "discovery." As for the impression conveyed by the author's paper, *i.e.*, that "Zambesi ulcers" are always connected in the first instance with the presence of muscid larvæ in the skin, such an opinion is not confirmed by my observations west of his district, where all ulcers, especially early ones, were closely scanned for Guinea-worms. On the other hand, I should say that the presence of the larvæ was exceptional.

I believe the author is right, however, in stating that the usual larva seen under the skin in this part of the world is distinct from *Bengalia depressa* (which, however, is also seen, but more rarely), for my specimens taken in the interior of Angola in nearly the same latitude, are certainly not to be identified with that species. Neither are they, on the other hand, to be confounded with the muscid larvæ, Blanchard's description of which is quoted in the article under discussion. Regarding this point, Dr. L. O. Howard, Chief of the Bureau of Entomology at Washington, writes (May 10th, 1905) to the Secretary of the American Society of Tropical Medicine concerning my specimens in the following words: "The larva removed with a pair of forceps from under the skin is most interesting. It appears not to be a Muscid, but its affiliations are with the *Sarcophagidæ*, the true flesh-flies; but I know of no record of the occurrence of a larva of this family under the skin of a human being. Still, new things are coming up all the while, and we may have here something absolutely novel." The *Sarcophagidæ* are important pests in this region, and I have seen the vivaparous females depositing their larvæ in wounds. I have also recently produced experimental destructive myiasis in goats, using *Sarcophaga africa*, Wied. and *S. albofasciata*, Macq. (*vide* the *Journal of Medical Research*, vol. xiv., No. 2. January, 1906, p. 439). It would seem probable that Mr. Ashley-Emile is dealing with some such fly as the above, or possibly with *Muscidæ*, as he believes. In any event, his finding of the larvæ, presumably in a number of ulcers, on the Zambesi (he, unfortunately, gives no figures) is an interesting observation, in spite of the unscientific and pompous manner in which it is announced, and, although he is unjustified in including without evidence (and without reference to the work of Harman, Ogston, and others, *cf.*, also my memorandum in this Journal for April 15th, 1905, p. 118), the veldt sore of other places in his category of maggot-caused phagedæna, yet it is to be hoped that fly larvæ will now be carefully looked for in all cases of African ulcer.

While waiting for confirmatory evidence, however, since in my own contiguous district cutaneous myiasis is not uncommon, while the formation of ulcers around the larvæ is, to say the least, very rare, and as I have seen no other evidence, in the course of considerable study of such conditions, to justify one in predicting a causal relation between the two conditions, I am unable to accept Mr. Ashley-Emile's etiological theories regarding veldt sore as established even for Zambesia, and agree with Mr. Old in suggesting that he should go over his work again, giving us case records, statistics, and what other exact data he has by him, instead of hasty generalisations and self-congratulatory phrases.

Hoping that you will pardon my occupying so much of your valuable space. Yours, &c.,

F. CREIGHTON WELLMAN.

South Angola.
April 15th, 1906.

Report.

SHANGHAI HEALTH DEPARTMENT.

ANNUAL REPORT FOR 1905.

ARTHUR STANLEY, M.D., B.S.Lond., in his annual report, just issued, on the health of Shanghai, states that "the past year has been the healthiest on record."

The death-rate amongst the 11,497 Europeans resident in Shanghai amounted to 11·2, as against 12·9 in 1904. Amongst a Chinese population of 452,716 the death-rate during 1905 was 14·2, compared with 19·2 during 1904.

Small-pox has been much less prevalent than for some time past; amongst Europeans, 41 cases were notified and 14 deaths registered; amongst Chinese, 246 deaths, as against 759 in 1904.

Cholera was unknown in Shanghai during 1905.

Typhoid fever attacked 50 Europeans, of whom 7 died. Dr. Stanley is of opinion that Malta fever occurs in Shanghai, in fact, in a recent letter to this Journal he substantiated the fact, and believes that several cases regarded as typhoid were really Malta fever infection.

Diphtheria.—Two deaths only occurred from diphtheria amongst Europeans although 22 persons were attacked. The reason for this low death-rate is no doubt due to the more general use of antitoxin, which is now produced in the Shanghai Health Laboratory.

Scarlet fever, a rare disease anywhere in Asia, except in Asia Minor, seems to have come to Shanghai to stay. Five cases were notified in 1905, in one of which the disease proved fatal.

Tuberculosis heads the list of fatal diseases, both among foreigners and natives, due to a great extent, no doubt, to overcrowding.

Plague cases were not met with in Shanghai during 1905.

Malaria of the benign tertian type occurred in Shanghai, but no deaths from the disease were reported. *Anopheles sinensis* is the variety of mosquito prevalent.

Dengue reached Shanghai in September of 1905, but the cases were neither numerous nor serious.

Beri-beri attacked 7 persons only, of whom 4 died. The municipal gaol was practically free from the disease during the year in question.

Dysentery caused but one death; there were three liver abscesses amongst Europeans.

The work at the Public Health Laboratory is evidently highly efficient, and the Health Department must be congratulated upon the extent and thoroughness of the work of sanitation which is rapidly bringing Shanghai to the forefront as a healthy place of residence for Europeans and for Chinese.

Reviews.

THE MEDICAL DISEASES OF EGYPT. By F. M. Sandwith, M.D., F.R.C.P. Part I. London: Henry Kimpton, 13, Furnival Street, Holborn, E.C., 1905. Pp. 316.

Dr. Sandwith has given us a book of a kind which is rare nowadays. It is written in a manner which

goes far to refute the accusation we are wont to hear frequently repeated, that medical literature in recent times has disassociated itself from all attempts at literary style. The whole book is interesting, and the matter is clothed in a manner at once fascinating and educative.

The opening chapter on "The Medical History in Egypt" shows a wealth of research and knowledge of which it is well known Dr. Sandwith is master. The chapter on Typhus reminds us that this disease still prevails in countries less favoured hygienically than our own. Where extreme poverty and ignorance of public hygiene obtain, there will typhus flourish, and until these are overcome typhus will continue.

Relapsing fever is traced historically, and at the present time when spirillar parasites are being discovered to be the cause of many ailments, it is well to have a description of its typical signs and symptoms.

Dr. Sandwith is of opinion that Egyptian town dwellers now suffer more from enteric fever than they did fifteen or twenty years ago. This is an experience in accordance with that of medical men in most tropical and sub-tropical countries. Whether this is due to more careful diagnosis, to Europeans carrying infection thither, or to an immunity acquired by natives in early years of life through having had the disease, is a matter of opinion at the present time.

Mediterranean Fever was not recognised in Egypt until 1883, when Dr. Sandwith recorded a case of the disease. Since then Mediterranean fever has been met with both amongst Europeans and natives.

Infectious Jaundice (Weil's disease) occurs as a rule only amongst the poorer classes of the community, but during epidemics of the disease any and every class are attacked. Dr. Sandwith is of opinion that the disease is carried by mosquitoes or other insects.

Scarlet fever is occasionally met with in Egypt, and measles is fairly prevalent.

Small-pox has committed fearful ravages in the Sudan during recent years, and in Lower Egypt during 1903 there were 2,118 cases reported, with 394 deaths from the disease.

Egypt is not free from an occasional outbreak of mumps.

Plague.—No mention of plague is contained in Egyptian papyri, but from the time of the third century B.C., the disease would appear to have recurred in Egypt at intervals, up to the present day.

Bilharziosis specially appertains to Egypt, for it was Dr. Bilharz, at Kasr-el-Ainy Hospital in Cairo, who first discovered the connection between hæmaturia and the Bilharzia parasite. The association between urinary calculi and this parasite, also first determined in Egypt, has revolutionised our idea of the pathology of these calculi.

A full description of Anchylostomiasis is welcome; and here, again, we have to thank an observer in Egypt, Dr. Looss, for his careful work on the subject, and for his brilliant observations on the mode of entrance of the larvæ of Anchylostoma by way of the skin.

The chapter on Pellagra closes the first volume, which is characterised by an accuracy of statement, a clearness of diction, and a knowledge of medical history as rare as it is pleasant to meet with.

THE BRITISH GUIANA MEDICAL ANNUAL FOR 1905. Edited by C. P. Kennard, M.D.Edin., M.R.C.S. Eng. Price 5s. Printed by "The Argosy" Company, Limited, Demerara.

We welcome this admirable medical annual, and congratulate the Editor and contributors upon the excellence of their volume.

PART III.—Transactions of the British Guiana Branch of the Medical Association for 1904 and 1905.

Anchylostomiasis.

The measures by which the disease can be stamped out are stated by Dr Godfrey to be:—

(*a*) The diagnosis of every case.

(*b*) The treatment of every case.

(*c*) The destruction of fæces of persons known to be infected.

(*d*) The prevention of contamination of the land round and about the labourers' residences, and the fields in which they work.

(*e*) The prevention of contamination of the drinking water.

(*f*) The distribution of leaflets containing a simple narrative of the disease.

(*g*) Making it an offence for any person to defæcate on any part of the land except those portions set apart for the purpose.

Dr. Aiken, in his article, enumerates the British Guiana mosquitoes (from Theobald) as follows:—

Myzomia lutzii; Stethomyia nimba; Cellia argyrotarsis, sub-species, *C. albipes; Megarhinus hæmorrhoidalis, M. separatus; Janthinosoma musica, J. lutzii; Stegomyia fasciata, S. luciensis; Culex tæniorhynchus, C. serratus, C. confirmatus, C. nubilis C. scholasticus, C. flavipes, C. fatigans, C. serratus; Melanaconion atratus vel Culex atratus; Tæniorhynchus fulvus* or *Culex fulvus, T. confinnis, T. fasciolatus;*

Mansonia tittilans: Dinocerites cancer; Uranotænia pulcherrima; Ædeomyia squammipenna; Hæmagogus cyaneus, H. albomaculatus; Dendromyia ulocoma, D. asullepta, D. (quasi) luteoventralis; Runchomyia frontosa; Sabethes remipes; Sabethoides confusus; Goeldia fluviatilis.

PHTHISIS IN THE CITY OF CALCUTTA DURING THE YEAR 1905. T. Frederick Pearse, M.D., F.R.C.S.

By a more careful notification of the causes of death in Calcutta, Dr. Pearse has been enabled to come to more definite conclusions concerning the prevalence of phthisis in that city than has been hitherto possible. A paragraph from the report places the result of the investigation strikingly before us. "Perhaps the most striking feature shown by our investigations is the excessive prevalence of phthisis amongst females. Among males the death-rate was only 1·4 per 1,000, which is almost as low as the general rate for England (viz., 1·3 per 1,000), whilst amongst females the rate was more than double, viz., 2·86 per 1,000. Equally noticeable is the extreme prevalence of the disease amongst Mahommedan females, the rate for whom works out at no less than 4·6 per 1,000. In England the death-rate is higher among males than among females. Mahommedan males had an only slightly higher rate than Hindus. The high death-rate from phthisis in Calcutta is entirely due to the fatality of the disease amongst females. Mahommedans of both sexes, however, suffer more than Hindus."

New Instruments, &c.

MESSRS. MAYER AND MELTZER, 71, Great Portland Street, London, W., have sent us their catalogue of instruments used in the practice of laryngology, rhinology, and otology. The catalogue is a very complete one, and shows the careful attention Messrs. Mayer and Meltzer have paid to this branch of surgical appliances. Accompanying the catalogue is a handsome extract from "hospital work in London," with illustrations showing the work rooms of the firm and their general hospital fittings.

Notes and News.

RATS AND PLAGUE.—At a meeting of the Lahore Plague Managing Committee it was resolved that an epitomised copy in pamphlet form of the article in the *Civil and Military Gazette* of March 24th regarding the transmission of plague by the rat-flea be printed and distributed through the medium of the various plague sub-committees.

WE are glad to know that the proposed South African Medical Association is likely to prove a success.

LIEUTENANT-COLONEL GILES asks us to inform his correspondents who may be sending him entomological material, that his address has been changed to 3, Elliott Terrace, The Hoe, Plymouth.

Personal Notes.

India Office: Arrivals in London of Indian Medical Officers.—Major J. Chaytor White, Captain W. H. Henrich, Major R. G. Turner, Lieutenant-Colonel O. H. Channer, Captain G. O. T. Groube, Lieutenant-Colonel C. J. Parkies, Captain J. D. Graham.

Promotions:

The following Promotions are made in the Indian Medical Service.—Majors P. Hehir, L. J. Pisani, W. R. Edwards, C. MacTaggart, G. I. H. Bell, I. Daly, H. Fookes, E. Hudson, A. W. Dawson, and W. H. Robson to be Lieutenant-Colonels; and Captains G. Lamb, H. Burden, C. H. Bowle-Evans, I. Fisher, E. S. Peek, S. A. Harris, E. C. Macleod, C. Thomson, D. W. Sutherland, and W. Selby, to be Majors.

Leave.

Major G. T. Birdwood, 2 m. 12 d.
Major W. D. Sutherland, 15 m. combined leave.

Postings.

Captain H. G. Walton, from Sitapur to Agra.
Captain J. Stephenson to be Civil Surgeon, Shahpur.
Captain D. H. F. Cowen to be Civil Surgeon, Murree.
Captain L. B. Scott officiates as Civil Surgeon, Cachar.
Captain P. F. Chapman, from Civil Surgeon Chihindwara to Akola.

Geographical Distribution of Disease.

As information arrives we publish, under this heading, the principal diseases met with in tropical and sub-tropical countries, so that those interested in the Geographical Distribution of disease may have a means of gathering information concerning the prevalent ailments in different parts of the world.

Philippines.

Cholera.—Manila has been free from cholera since February 21st. During the present outbreak, which commenced on August 23rd, 1905, there have been 282 cases of cholera with 250 deaths from the disease in the city of Manila. In the provinces there were 3,742 cases of cholera reported, with 2,807 deaths.

Leprosy.—Two cases of leprosy, which were treated with the X-rays, and in which the symptoms disappeared for a considerable time, have proved disappointing, a relapse having occurred in both cases.

Small-pox.—The provinces of the Philippines, in which vaccination was thoroughly carried out, have remained almost free of small-pox, but in unvaccinated districts the disease has prevailed extensively lately.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

TSETSE-FLIES AND TRYPANOSOMES.

Minchin, Prof. E. A., who, it may be remembered, was deputed to Uganda by the Royal Society to study the relations between *Trypanosoma gambiense* and *Glossina palpalis*, gives, in his pamphlet of eight pages, the results he has obtained at Entebbe, in association with Lieutenants Gray and Tulloch, R.A.M.C. Previously to his joining them, these two officers believed they had discovered evolutionary forms of the *T. gambiense* in the flies.

Minchin's results are, however, somewhat disappointing, as he believes the forms they observed have no connection with the trypanosome.

Some 8 per cent. of the tsetse-flies found in the small island of Kimmi were infected with these supposed evolutionary forms, two distinct species, one resembling the trypanosomes of birds and the other that of mammals, being distinguishable; but no corresponding vertebrate host could be discovered, and inoculation of animals capable of harbouring *T. gambiense* gave negative results. On this account it appears more probable that these forms, which are of the *Herpetomonas* type, are really special parasites of the tsetse-flies, like the herpetomonads of ordinary flies which do not suck blood.

Some were also found in a *Glossina* born in the laboratory, and which had been fed only on the blood of a domestic fowl, so that it seems probable that these herpetomonads can be transmitted by hereditary infection.

Attempts to infect flies by causing them to bite infected animals gave doubtful results. Changes resulting in the differentiation of what seemed to be male and female types went on for forty-eight hours, but then the process came to an abrupt halt, and by the end of seventy-two hours few or no trypanosomes remained in the stomach or demonstrable by dissection, though it is possible that sectionising may yield different results. We are therefore still without any proof of the existence of any developmental cycle within the tsetse at all comparable with that of the malarial parasite in the mosquito. If any such cycle take place, it is presumable that the infection of the fly would require a certain interval for development after feeding with infected blood, but no such periodicity can be shown to exist. The *Glossina* can, however, undoubtedly act as a simple vehicle. Thus experimenting with rats seriously infected with a trypanosome (probably *T. Brucei*) by causing flies fed on them to bite healthy animals, four successes were obtained out of five experiments, while using *Stomoxys* only one success in four resulted. It is further noteworthy that while the trypanosomes survive seventy-two hours in *Glossina*, they persist but twenty-four hours in *Stomoxys*.

Prof. Minchin therefore inclines to the belief that the tsetse acts simply as a vehicle, and points out that if it really played the part of an intermediate host, the spread of the disease in human beings would probably be far more rapid than it is.

"Zeits. f. Hygiene," T. lii., p. 31, with 2 plates.

THE PATHOLOGICAL HISTOLOGY OF EXPERIMENTAL NAGANA.

Sauerbeck, Ernst. The author compares the pathological histology of trypanosomiasis with that of tropical splenomegaly from the *Piroplasma Donovani*. He examined the organs of rats, guinea-pigs, rabbits and dogs infected with *Trypanosoma Brucei*, but found nothing to add to the results of previous investigators. In the blood no degenerative processes are normally observable in the trypanosomes, but such are commonly to be found in the internal organs, notably in the spleen, lymph glands, bone-marrow, and liver, and less markedly so in the lungs.

The author regards the amœboid and other forms described by Plimmer and Bradford, and which they considered as stages in a complicated system of evolution of the parasite, as merely of the degenerative character, and further points out their close resemblance to the Leishman-Donovan bodies. Prof. Mesnil, commenting on the paper in the *Bulletin of the Pasteur Institute*, however, points out that though the resemblance between the two forms is undeniable, it cannot warrant our regarding tropical splenomegaly and trypanosomiasis as belonging to the same category of disease. The Leishman-Donovan bodies are a normal and definitive form for the human organism, and, despite the fact that cultivations of the *P. Donovani* give rise to flagellate forms, never include any trace of flagellate forms *in vivo*. The smaller bodies found in trypanosomiasis, on the other hand, are no part of the evolution of the parasites, but are merely stages of their degeneration, which rapidly disintegrate, while the Leishman-Donovan bodies maintain a perfect integrity. The involution forms of the trypanosomes are usually intracellular, and in course of digestion by phagocytes and Sauerbeck's own descriptions clearly show that the histological changes in the organs are due to proliferation of the latter, but he nevertheless insists on the complete resemblance between these histological elements and those found in tropical splenomegaly.

The phagocytic action of the mononuclear cells can be demonstrated by making an intraperitoneal injection of trypanosomes. The macrophages engulf the perfectly mobile parasites, which take a rounded form in their interior, and the same process evidently occurs in phagocytic organs, which behave in this case exactly as they do in malignant carbuncle, typhoid fever, or plague.

"Atti della Societa per gli Studi della Malaria," T.vi., Rome, 1905, 666 pages.

The volume is made up of the reports for 1904 of a number of writers who for the most part concern themselves with the results of preventive measures for malaria.

On the railways protection by metallic gauze for employees continues to be favourably reported upon, but it is pointed out by V. Polettina that for private individuals the expense is prohibitive, except in the case of the well-to-do. This contributor also considers that the dangers of rice cultivation are exaggerated, but it is obvious that this opinion may be based on local peculiarities of the district under his observation.

A large portion of the volume is occupied with reports on the results of the prophylactic administration of quinine, and the opinions of the various writers appear to be uniformly favourable. In many cases the sickness among the unprotected was three times as great as among those taking quinine, and in view of the large numbers treated, many of whom must have occasionally forgotten to take their dose, this must be considered highly satisfactory.

The annual cost per head, according to G. Soliani, is about 2.20 lire, or 1s. 10d.

The year's results are summed up by Prof. Celli in an able article. Judged by effects on the general population, the year 1904 was a bad one. In the north, benign tertian predominated, but in the south the Roman Campagna malignant tertian was commonest. Cases of quartan fever where irregularly distributed. In an epidemic, cases of relapse are always more numerous than those of primary infection. In the Roman hospitals cases of relapse were very common in July and August, and diminished suddenly in September, whereas usually relapses are most common in September and October. Primary infections were most numerous in July and August.

Although many contributors witness to the efficacy of Koch's method of large doses every eight or nine days, Prof. Celli appears to give his verdict in favour of the daily administration of moderate doses of 6 or 8 grains.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the JOURNAL OF TROPICAL MEDICINE should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communications.

A FURTHER REPORT ON MEASURES TAKEN IN 1901 TO ABOLISH MALARIA FROM KLANG AND PORT SWETTENHAM IN SELANGOR, FEDERATED MALAY STATES.

By E. A. O. Travers, M.R.C.S., L.R.C.P.,
State Surgeon, Selangor, and
Malcolm Watson, M.D., D.P.H.,
District Surgeon, Klang.

The measures taken to abolish malaria from Klang and Port Swettenham in 1901 and 1902 by the extermination of mosquitoes by means of extensive drainage and other operations tending to do away with their breeding grounds, have been fully reported on in the Journal of Tropical Medicine of September 15th, November 10th, and December 1st, 1903, and April 1st, 1904.

It is proposed in the present article to show that the expenditure undertaken by Government, with a view to improving the health of the inhabitants of these towns, has been fully justified by the results which the experience of the last four years justifies us in concluding will be of a permanent nature.

For the information of those who have not read the previous articles on this subject, a brief account of the works carried out may be of interest.

Port Swettenham.—An area of about 110 acres, formerly low-lying, swampy land covered with mangrove trees, has been cleared and carefully drained. In the neighbourhood of the railway, Government buildings, and town site, a considerable area has been filled in and levelled, partly to do away with the breeding grounds of mosquitoes and partly to provide building sites. The whole area not occupied by buildings or roads is now covered by grass.

The total expenditure on works other than the preparation of building sites has been (to the end of 1905) £7,000, and the annual cost of upkeep of drains, &c., is approximately £40, for clearing earth drains and for town gardeners, £100.

Klang.—The area affected by the operations is about 332 acres. Twenty-five acres of virgin jungle and 80 acres of dense secondary growth (in places 30 to 40 feet high) have been cleared and 36 acres of permanent swamp have been drained. The areas cleared are now mainly under grass.

The total expenditure to end of 1905 has been £3,100, and the cost of annual upkeep is about £60 for clearing earth drains, and £210 for town gardeners.

As will be seen by the following statistics of cases of malaria treated at the District Hospital, Klang, the improvement in the health of the inhabitants of the areas treated began immediately after the completion of the drainage and other works, and has continued to date.

Table showing the number of cases of malaria admitted to the Klang Hospital from Klang Town and Port Swettenham, as compared to the number of cases admitted from other parts of the district :—

Residence	1901	1902	1903	1904	1905
Klang	334	129	48	28	12
*Klang and Port Swettenham	88				
Port Swettenham	188	70	21	4	11
Other parts of District ..	197	204	150	266	353
Total	807	403	219	298	376

* Certain persons lived some nights in Klang and some in Port Swettenham.

The following table shows the number of deaths from fever and other diseases which have occurred at Klang and Port Swettenham during the last six years. The population in 1901 was about 4,000, but has largely increased since.

Deaths in Klang and Port Swettenham corrected for Deaths in Hospital.

Year	1900	1901	1902	1903	1904	1905
Fever..	259	368	59	46	48	45
Other Diseases ..	215	214	85	69	74	68
Total	474	582	144	115	122	113

It will be noted that the remarkable improvement in the health of the inhabitants which occurred in 1902, immediately after the anti-malarial works had been completed, has been well maintained.

The following table shows the number of deaths occurring in the district of Klang, excluding the town of Klang and Port Swettenham. (Population 14,000 in 1901, since largely increased.)

Deaths in Klang District, excluding Klang Town and Port Swettenham.

Year	1900	1901	1902	1903	1904	1905
Fever..	173	266	227	230	286	351
Other Diseases ..	133	150	176	198	204	271
Total	306	416	403	428	490	612

These figures are especially valuable as a proof that the marked improvement in the health of the inhabitants of the town of Klang and Port Swettenham is due to the anti-malarial measures carried out, and not to a general improvement in the health of the district.

In Klang and Port Swettenham we have 368 deaths due to fever in 1901, and 45 only in 1905; whereas in the rest of the district, which has not been dealt with by any special anti-malarial works, we have 266 deaths due to fever in 1901, and 351 in 1905.

It may here be mentioned that Klang is a large planting district about 380 square miles in extent, that it is mainly low-lying flat land utilised for the cultivation of rubber, and that it would be almost impossible to protect the scattered population from malaria by

drainage and filling in swamps. A great deal is now being done on most of the estates by regular administration of quinine, and also by protection from mosquitoes.

Malaria in children as evidenced by Examination of blood.—No better indication of the presence or absence of malaria in any given district can be obtained than by a systematic examination of the blood of children.

The following details of the results of examinations carried out by Dr. Watson in 1904 and 1905 are of considerable interest :—

Results of Examination of Blood of Children in Klang and Port Swettenham (specially Drained Areas).

Improvement in Health of Government Employées.—The remarkable way in which the health of the Government employées residing at Klang and Port Swettenham has been affected is well shown by the following figures. It may be mentioned that in 1901 the number of persons residing at Port Swettenham, employed by Government, was 176, and in 1904, 281.

Table showing Number of Sick Certificates and Number of Days' Leave Granted on account of Malaria.

	1901	1902	1903	1904	1905
Certificates	236	40	23	14	4
Days of Leave	1,026	198	73	71	30

The conclusions to be arrived at from the figures given in this report are very evident :—

(1) Measures taken systematically to destroy the breeding place of mosquitoes in the towns, the inhabitants of which suffered terribly from malaria, were followed almost immediately by a general improvement in health and decrease in death-rate.

(2) That this was due directly to the works carried out, and not to a general dying out of malaria in the district, is clearly shown by figures pointing out that while malaria has practically ceased to exist in the areas treated, it has actually increased to a considerable extent in other parts of the district where anti-malarial measures have not been undertaken.

The fact that the statistics for 1905 are even more favourable than those for 1902 is very strong evidence in favour of the permanent nature of the improvement carried out.

If, as it is hoped, malaria has been permanently stamped out from Klang and Port Swettenham by works undertaken in 1901, our experience in the Malay States should be of value to those responsible for the health of communities similarly situated in many other parts of the world.

THE ANATOMY OF THE BITING FLIES OF THE GENERA *STOMOXYS* AND *GLOSSINA*.

By Lieut.-Colonel G. M. Giles, I.M.S. (Rtd.).

(*Continued from p.* 185.)

The abdomen is a good deal shorter than the wings, and, seen from above, appears to be composed of only four segments, the juncture between the first two being hidden and the remaining four concealed by being curled under in the male or hidden in the telescoped ovipositor of the female. In the gorged insect, the whole of the ventro-anterior portion of the cavity is taken up with the enormous crop, which in males, when distended, occupies almost the entire space, leaving the other viscera crowded into a comparatively small space behind and above it. When empty of food it contains a certain amount of air, and Lieut. Tulloch's account, transcribed below, must be taken as referring to it in this condition : As his admirable account, which entirely agrees with my own observations, is very brief and to the purpose, I cannot do better than transcribe it, altering the nomenclature, where necessary, to that hitherto employed. He says :—

"The midgut runs down into the abdomen of the fly as a narrow tube of uniform diameter until it reaches nearly to the posterior border of the crop. At this point it dilates to several times its former diameter, its wall at the same time becoming thinner. It is proportionately shorter, less coiled, and more distensible than in *Glossina*, being about three times as long as the fly itself. This dilated portion has three simple coils, which lie superposed in the middle of the abdomen, and it then gradually narrows, continuing as a uniformly narrow tube down to the rectum. The narrow lower intestine has variable bends, but is not coiled. The rectum is a dilated cone-shaped cavity, with its apex towards the anus. Its walls are transparent, and through them are seen the four trumpet-shaped rectal papillæ, the narrow ends of which are pointed towards the anus, a single trachea entering the base of each. Below the dilatation, the rectum is continued to the anus as a short, narrow tube. In the female the distal part of the rectum runs within the ovipositor, the anus opening between the last segment of the ovipositor and the terminal plate. In the male the ejaculatory duct passes over it dorsally from left to right and runs anteriorly to enter the penis. The appendages of the alimentary canal are the Malpighian tubes, the crop and the salivary glands. The Malpighian tubes arise from a

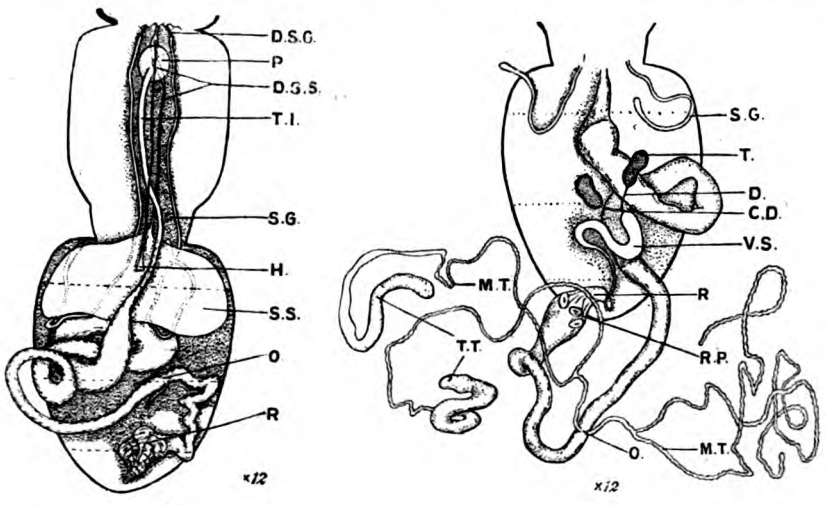
shallow constriction which marks the point of junction between the midgut and metenteron, and it, together with the true proctodeum, comprises in length about one fifth of the abdominal intestinal canal. Two of the tubules arise on either side from a short, common tube, all four being about the same length. The two arising from one side have thickened terminations, some four times greater than a



1. 2.

FIG. 29.—Dissections of the abdomen of *Stomoxys*, after Lieut. Tulloch, seen from above :—(1) with the parts almost *in situ*; (2) with the alimentary canal unravelled; CD, common seminal duct; D, seminal duct; DSG, duct of salivary gland; DSS, crop duct; H, dorsal vessel; MT, malpighian tubes; O, junction of distal intestine and metenteron; P, proventriculus; R, rectum; RP, rectal papillæ; SG, salivary glands; SS, crop; TI, chyle duct; *tt*, dilated ends of left malpighian tubes; VS, vesicular seminalis.

salivary gland, and lie in the pericardial sinus; those of the other are of uniform thickness, and end amid the fat body of the lower abdomen. The salivary glands in the abdomen are ventral to the crop, and seen from above only a knuckle of each projects beyond it, and then turned forwards to end close to the waist in slightly bulbous ends. Except for this angular bend the glands are straight, and even if extended, would not reach to the end of the fly.

Throughout its length the mucosa of the intestinal canal is composed of a single layer of epithelial cells. The wide thoracic portion of the midgut of the blow-fly, called by Lowne the chyle stomach, is in *Stomoxys* a quite narrow tube, though it has the same structure as in the former insect. Both it and the wide proximal intestine is composed of a layer of cells whose components vary a good deal in size and form, according to the stage of secretory activity in which they have been fixed. In the thoracic portion the muscular coat is fairly distinct, and both the longitudinal and circular fibres are arranged at intervals, leaving spaces where there is only epithelium; but the pouching out of the lining into these spaces is by no means as marked as in the blow-fly, so that even in proportion to its size this part of the gut has not as strongly granular an appearance when viewed with a dissecting lens. The dilated part of the proximal intestine has an epithelial lining (plate i., fig. 1) of much the same character, and both in it and the narrow transparent part that follows it the muscular coat is very ill marked, and often appears quite absent in sections; though where the transition to the structure of the narrow part occurs, the circular coat becomes very distinct (fig. 2). The narrow part is lined with cubical cells of regular form (figs. 3 and 4), and has a very distinct limiting membrane towards the lumen of the tube.

The metenteron, on the other hand, is strongly muscular, and is structurally divisible into two distinct portions. For the first and greater part of its length it is lined with a distinct cuticular lining, the epithelial elements of which are scarcely discernible. In the ordinary contracted condition of the tube, this is wrinkled into deep folds, in the interior of which are strong longitudinal muscular bands (pl. i., fig. 5), and outside these is an equally strong coat of circular muscular fibres. The last short portion before the rectal valve is of similar structure, but here (fig. 6) the cuticular lining has become distinctly chitinous, and has developed into a curious armature of powerful spines, the function of which I am unable to conjecture. There is, however, nothing generically peculiar in this structure, which is, I believe, found throughout the Muscidæ. The "rectal valve" between this portion of the intestine and the rectum is lined with similar spines, and is surrounded by a muscular thickening. At first the rectum is tubular, and its chitinous lining has a distinct basis of cubical epithelial elements; but after passing a quasi-sphincter formed by a thickening of the muscular coat, it expands into a large cavity which lies on the right side just under the interior abdominal terga. This dilated portion of the rectum is lined by a delicate chitinous membrane, the epithelial basis of which is not easily demonstrable, and is covered with a network of muscular fibres closer meshed, but of the same general character as that of the crop. This dilatation contains the four rectal papillæ, which are four cylindrical projections ending in blunt conical points, lying two and two lengthwise in the intestine. They resemble a good deal the rectal gills of certain aquatic larvæ, but according to Lowne subserve the renal function, as he has found in them a substance related to uric acid. Their general form may be seen from the dissection (plate i., fig. 7) of the two right-hand papillæ (the figure being reversed), and in section (plate i., fig. 8) are seen to be formed of very large columnar cells surrounding a core of delicate mesodermic tissue in which is imbedded a large trachea. Behind the papillæ the rectum contracts to a mere slit, and the absolute anus is guarded by a strong sphincter of unstriped muscle.

The malpighian tubes which enter the bowel at the point of junction of the proximal intestine with the metenteron hardly differ from those of the mosquito even in size. Their large pigmented cells and slit-like lumen, zig-zag longitudinally, must be familiar to most students of tropical medicine from their dissections of those insects. Lowne advances strong reasons for believing that

their function is hepatic, and not, as usually supposed, renal.

The crop has an elastic pigmented chitinous membrane covered with an open and rather irregular network of unstriped muscle, and its ventral side is connected with the abdominal sterna by a number of single obliquely-directed striped muscular fibres. Its whole structure is such that though clearly contractile, it is obviously absolutely incapable of active dilatation, so the name of "sucking stomach," which is sometimes applied to it, should be carefully avoided.

In *Glossina* the abdominal intestine is longer, larger, and in every way more voluminous, and the secretory area of the dilated portion has its surface enormously increased by deep infoldings of very large epithelial

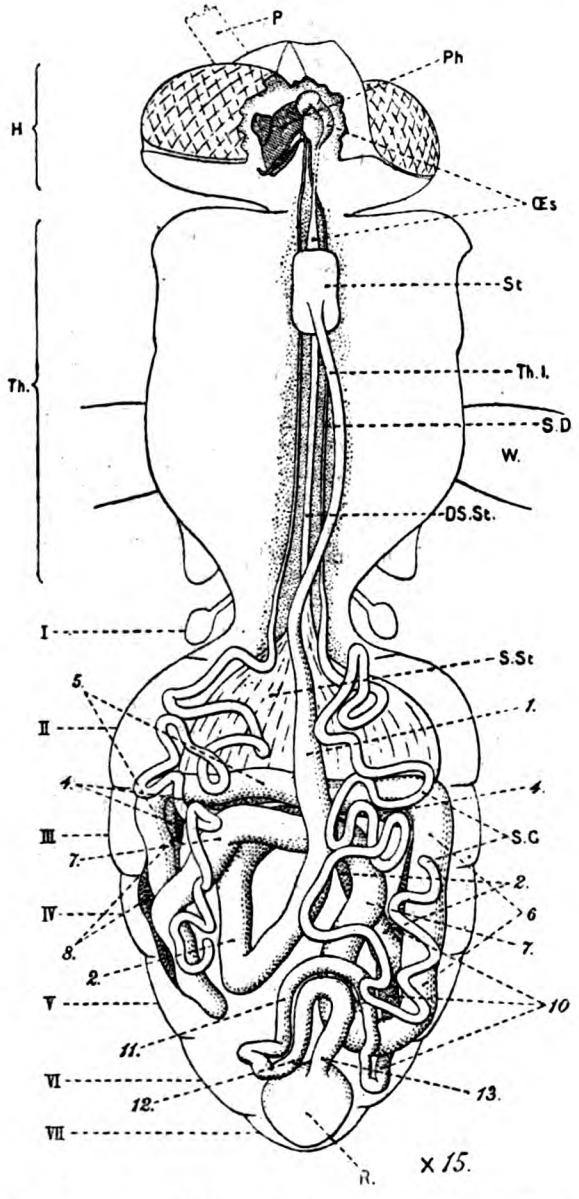


FIG. 30.—General view of the digestive tract of Glossina palpalis, as seen in dorsal view without disturbing its parts. The heart and over-lying tracheæ and fat-body are removed in the abdomen, also the muscles in the thorax, and the brain and other parts of the nervous system are omitted from the drawing. The head is turned round to the left, in order to show the pharynx, &c., in three-quarter side view. *Ph*, pharynx; *Œs*, œsophagus (the portion which passes through the brain being represented with a dotted outline); *St*, stomach; *Th*, *I*, thoracic intestine, pulled over to the right, in order to show the duct of the crop lying beneath it; *S*, *D*, salivary duct; *DS*. *St*, duct of; *S*, *St*, the sucking stomach; *S*, *G*, salivary gland (that on the right is drawn from a specimen in which the gland was more developed than in the case of that drawn on the left); 1 13, limbs of the abdominal intestine (see fig. 31); *R*, rectum. (After Minchin.)

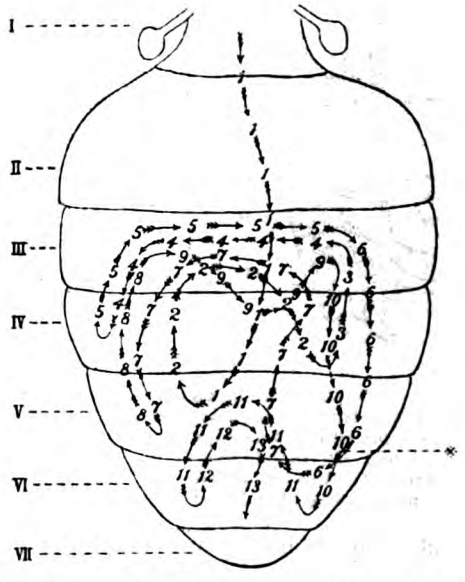

FIG. 31.—Diagram to show the various limbs (1—13) of the abdominal intestine, and their arrangement in the abdomen. The asterisk * denotes the point at which the Malpighian tubules arise in the tenth limb. (After Minchin.)

elements. The two figures herewith reproduced from Professor Minchin's paper will, in the light of what has been said of the allied species, give a sufficient idea of the arrangement of the parts, and as he proposes to write a paper on the histology of the genus, any further discussion of the subject here is superfluous.

The enormous development of the intestine is somewhat surprising in a species subsisting on so nutritious a diet as blood.

The vascular system.—What is found by the writer the readiest plan of demonstrating the dorsal vessel of a dipterous insect is to compress the insect between the fingers and thumb, at the same time, as far as possible, strengthening out the dorsal curve, and then to snip off the mid-dorsal portion of the abdomen by a single stroke of a pair of sharp scissors.

The portion removed is then placed in water, under the dissecting microscope, and as much as possible of the fat body picked away. The facility of this latter operation, however, differs greatly in different species, but is especially difficult in *Stomoxys*. Lieut. Tulloch, in his paper, notices this point. He says:—

"Though several stained preparations were made, it was impossible, owing to the fat body, which obscured all detail, to count the chambers and cells in the heart wall. They seemed, from a comparison of all preparations, to be re-

duced in proportion to the smaller number (four) of abdominal segments possessed by *Stomoxys*."

As compared with *Glossina*, I am inclined to agree with Lieut. Tulloch as to the number of chambers, but must confess great uncertainty on the point.

Referring to *Glossina*, Prof. Minchin writes as follows :—

"The vascular system consists of the heart, in the abdomen, and its continuation, the thoracic aorta, in the thorax.

"The heart occupies the five anterior segments of the abdomen, and is situated dorsally immediately below the plates of the terga. It is so imbedded in the fat body and pericardial tissue that not much can be made out of its structure by dissection alone, and examination of it mounted as a preparation for the microscope is necessary. It can then be seen to have five chambers, each with a pair of ostia and a pair of alary muscles, corresponding to the segments in which it lies. The alary muscles pass out at right angles to the axis of the heart, and can be traced through the fat body to their attachments at the external lateral margins of the tergal plates.

"The hindermost chamber of the heart appears to end blindly posteriorly. A little way in front of the hinder end are attached the two large alary muscles, the largest of the whole series; not far in front of these again are the two ostia, on the sides of the widest part of the chamber. In front of the ostia the lumen of the heart narrows rapidly, and to the narrow portion is attached the next pair of alary muscles, lying in the hinder part of segment 4. This arrangement is continued in segments 2, 3, and 4, the dilated portion of the chamber, with the ostia, occupying the middle of the segment, while the alary muscles, attached to the constrictions between the chambers, lie in the posterior regions of the segments. The alary muscles of these three segments are of moderate size. In segment 2 the heart receives a pair of tracheal tubes, right and left, which come to it opposite the ostia, and fork at once into branches running forwards and backwards. The alary muscles corresponding to the first abdominal segment are very small and difficult to make out, and the region of the heart to which they are attached does not show the slightest diminution or constriction of its lumen, as is the case in all the chambers posterior to it. In front of the first pair of alary muscles, at the usual interval, are the two ostia, quite similar to those of the other chambers. In front of the first pair of ostia the lumen of the heart narrows to form a thin-walled vessel, which passes through the waist to become the artery which I have termed above the thoracic aorta. This last runs along the thoracic intestine on its dorsal side, and is continued over the stomach, remaining apparently quite independent of the digestive tract, and only loosely attached to it, until it reaches the œsophagus. Here it is firmly attached and becomes considerably dilated. A short distance in front of the stomach a conspicuous cushion-like mass of large cells lies over the aorta. At first I took this structure for a ganglion, but it appears to be a sort of lymphatic gland, judging from its appearance in sections. The thoracic aorta is apparently continued through the neck into the head, but I have not been able to follow its course further than the thorax.

"The microscopic examination of the heart shows further that its floor is composed chiefly of fusiform cells resembling unstriped muscle fibres, while its sides are made up of gigantic cells with nuclei of corresponding proportions. These cells are arranged with perfect regularity, and in a manner exactly similar on the two sides of the heart. Each ostium is formed by two cells, which are of small size when compared with the huge cells building up the wall of the heart, but are very large when compared with the cells of the surrounding tissues. Two of the giant cells intervene on each side between the hinder end of the heart and the fifth pair of alary muscles; two more between these muscles and the ostia next in front of them; and so on with unfailing regularity all the length of the heart, each ostium being separated from the alary muscles next in front or behind by just two giant cells. In front of the first pair of ostia are found two cells of the usual size on each side, then a pair of slightly smaller cells, which pass on into the walls of the thoracic aorta. Thus the entire wall of the heart is built up of 23 pairs of giant cells, not counting the ten couples of smaller cells which compose the five pairs of ostia: to wit, four pairs to each of the five chambers, two additional pairs behind the fifth pair of alary muscles, and one pair anteriorly, making the transition to the thoracic aorta. In view of the fact that the thoracic vessel is itself to be considered as a modified anterior portion of the heart, it is interesting to find that its delicate wall contains very large, flattened nuclei, arranged in pairs right and left.

"The alary muscles consist of delicate fibrils, arranged in an irregular fan-like manner, uniting into a stout muscle-fibre which is distinctly striated."

The above description, in the main, applies equally well to *Stomoxys*, and is in entire agreement with such observations as I have made on *Glossina*, except as to the floor of the heart being composed of "fusiform cells resembling unstriped muscular fibres." It is believed that the statement is referable to the appearances presented by dissected specimens, which always include the pericardial septum, which, seen in optical section, certainly conveys the impression described. As the result of the examination of sections, the writer believes that Lowne is correct in describing the dorsal vessel of Diptera as a hollow muscle, composed at the most of two cells in any single transverse section.

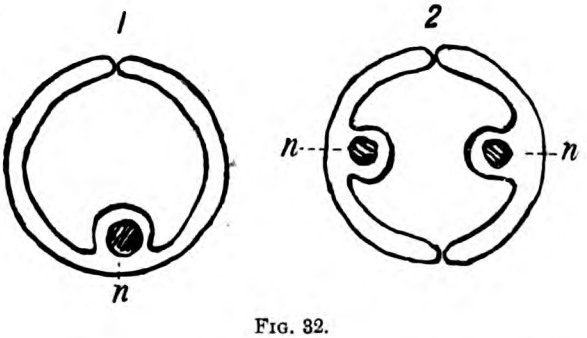

FIG. 32.

Lowne's conception of the heart of the blow-fly, as gathered from his book, may be diagrammatically represented as in fig. 32, each large nucleated cell being provided with lateral expansions which meet above in the middle line. In *Glossina*, however, my sections appear to show that there are always two cells in any individual transverse section; and that, as Professor Minchin states, they are symmetrically disposed in pairs, but I can find no difference in structure in the upper and lower walls, and so doubt the existence of a structurally differentiated floor to the organ.

In *Stomoxys* there are also usually two cells in any individual transverse section, but they are placed not opposite each other, but alternately, so that only one of the oblong nuclei is ever visible in a single section, and opposite the middle of each the entire circumference of the tube is presumably formed by that cell alone. The number of giant cells would therefore be less than in *Glossina*; but, like Lieut. Tulloch, I have been quite unable to count them, and the heart is so

frequently damaged in serial sections of the entire insect that they throw no further light on the point beyond the fact that the nuclei are certainly opposite in *Glossina* and alternate in *Stomoxys*.

Seen in transverse section, the entire wall of the heart has an uniform structure but for the nuclei of its component giant cells. On close examination the protoplasm is seen to be broken up into masses of irregular prismatic section which form the cross view of the longitudinal striation, which is distinctly visible in longitudinal optical section. Plate i., fig. 9, represents a section of the anterior part of the heart of *Stomoxys* (Banded form ♀) in which, on the right side of the figure, one of the nuclei of that side is cut across, while that of the opposite side is divided beyond the nucleus, and so represented only by a slight projection. In pl. i., fig. 10, is shown a similar section of the back part of the heart of *Glossina*, in which the nuclei of the two component cells are divided at about a corresponding level. It is noteworthy that in this insect the cells project much more into the lumen of the tube than in *Stomoxys*, so that at their thickest part they appear connected with the body of the cell by a comparatively narrow pedicle. Fig. 11 is a semi-diagrammatic representation of a valve in *Glossina* as seen in optical section. It will be noticed that it differs somewhat from Prof. Minchin's account of the number of component smaller cells, in that three instead of two are represented as forming the valve, but the appearances presented by a structure seen in this way are notoriously deceptive, and I have no disposition to press the point. In *Stomoxys* I have as yet failed to obtain any satisfactory view of the valves. (*To be continued.*)

Correspondence.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

DEAR SIRS,—The following case may be of some interest to younger members of the profession in the tropics. A blacksmith, S., aged 35, from Jerusalem, well-known as one of the strongest men in the place, consulted me three or four months since for abdominal pain. Nothing being much wrong with him I prescribed a purge with santoninum. Next day he came back much pleased with the relief he had experienced, but I could hardly understand why he was so pleased. However, next day his symptoms recurred, it being cold weather and no history of fever and chills being given, the idea of malaria never occurred to me.

Two days later I received an urgent message, and later an offer of double the usual fee if I would go at once to see him. He was doubled up with abdominal pain and had been very sick, but there was nothing in the abdomen to account for it. Finding he had a temperature of 103°, I took a slide of his blood, warning him that if the examination were negative he must go to hospital. The matter was cleared up, greatly to my surprise, by my finding numerous tertian parasites and gametes, and a few doses of quinine soon ended the attack; the spleen was not at all enlarged.

I am, &c.,
J. CROPPER.

Ramallah, Jerusalem.
June 13th, 1906.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

SIRS,—In the course of my work with films from yaws lesions and glands, I have been able to confirm some at least of the observations of Dr. McLennan (*British Medical Journal*, May 12th, 1906), connecting spir. pallida with cytorrhyctes luis.

The enclosed sketches were taken from a smear of serum of a cleaned frambœsia, stained in Giemsa solution. They show in the briefest way the almost certain identity of the organisms found in syphilis and yaws.

The study is a difficult one, especially for a medical officer "fed up" with work, and I have been handicapped by want of higher powers. The London School of Tropical Medicine lent me a $\frac{1}{18}$, but unfortunately they required it again before one had got well into the research.

I am now awaiting new lenses, and hope to be in a position to report progress later.

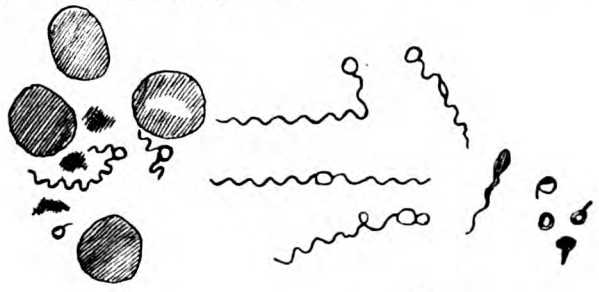

FIG. 1.
A group as actually seen.

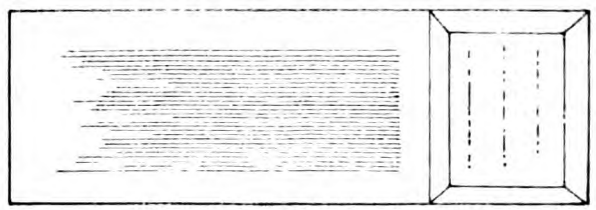
C. W. BRANCH, M.B.

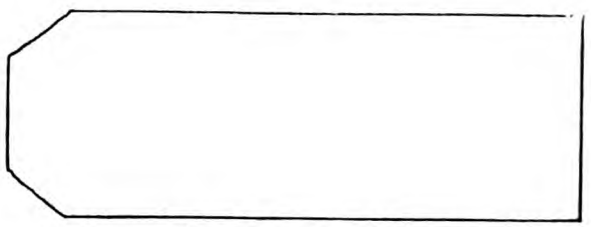
To the Editors of the JOURNAL OF TROPICAL MEDICINE.

DEAR SIRS,—I enclose a slide showing a method of preparing films of blood which I have found very useful in practice. It has the following advantages:—(1) Great simplicity. (2) The film can be made at any distance from the edge of the slide. (3) In an emergency the ear can be cut with the edge of the slide in the absence of knife or needle. An ordinary ground glass slide is clipped by scissors so that one end is narrowed to the desired width of the film, this varying according to the particular mechanical stage in use. The film is made in the ordinary way as described by Daniels, *i.e.*, with the end of the slide.

I am, &c.,
J. CROPPER, M.D.



Film made by slide below.



Slide cut to desired width.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 ,, ,, 6/-;
200 ,, ,, 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 ,, ,, ,, 11/-;
200 ,, ,, ,, 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

JULY 2, 1906.

HYGIENIC MEASURES AGAINST SYPHILIS.

HARBEN LECTURE No. III.

PROFESSOR METCHNIKOFF dealt with syphilis and its prophylaxis in manner at once practical and scientific. Syphilis, like tuberculosis and influenza, is directly contagious from man to man, requiring no intermediary host to transmit the infection. At first sight it would seem an easy problem to check the spread of a disease which is conveyed by intelligent human beings by appealing to their intelligence, compared with what would seem the unsurmountable difficulties of preventing the spread of disease by, say, irresponsible insects serving as intermediary hosts in such diseases as malaria, filaria, yellow fever, and others. Yet it is not so; animal pests can be destroyed, mosquitoes can be prevented breeding their kind, but appeal to man's intelligence is well nigh useless in conflict with the passion which determines the infection of syphilis. The disease is, as a rule, contracted by quite young men and women at an age before acquaintance with the world has enabled them to grasp, or it may be to have heard spoken of, the meaning of syphilitic infection or how it is conveyed.

In Western Europe one sees for the most part the individual attacked; in Russia the whole family may suffer. In remote villages the disease, once introduced, not infrequently spreads from child to mother, to grandparents, and to brothers and sisters by kissing the infant. After pointing out the destructive influence syphilis has upon the body tissues and upon duration of life, Professor Metchnikoff dealt with the prophylaxis of the disease. The proposal that young persons should be told the meaning and danger of promiscuous intercourse and the terrible effect of acquired syphilis was dismissed as impracticable, and as wholly inefficacious and undeterrent. Medical inspection of women likely to spread the disease is also an inefficient method, as much of the infection takes places amongst quite young girls before they become declared public prostitutes. Early marriages are not calculated to diminish the evil, owing to the extreme youthfulness of the great proportion of syphilitics, the disease being contracted before even the age at what may be called youthful marriages are wise or usual. Professor Metchnikoff then proceeded to show that the only prophylactic of practical value is the early application of mercury. By experiments on animals, and even on men, by several observers it has been shown that an inunction of metallic mercury, calomel, white precipitate, or salicyl-arsenite of mercury with lanolin of the strength of 1·3 or 1·4 gives satisfactory protective results. Inunction should be thorough, persisted in for four or five minutes, and applied between one and twenty hours after inoculation. The result of experiments is that mercurial ointments may certainly be useful prophylactics against syphilis in all those cases where a contact, however little suspicious, has taken place. Instead of blue ointment, which causes much irritation of the skin and mucous membranes, the use of salves made up with non-irritating mercury salts above mentioned, should be recommended.

Professor Metchnikoff dismisses the contention of persons who would punish sexual delinquents by allowing the disease to run its course as prudish, and sums up the matter by pointing out the effect of allowing the opinions of persons with such beliefs to be heard, in these words:—"Persons who look apon the prophylaxis of syphilis as immoral should apply the same reasoning to the use of antiseptics in midwifery, because it facilitates criminal abortion." Further, he states: "No considerations of a moralising tendency should be opposed to the prevention of so disastrous a calamity as syphilis. True morality ought rather to contribute as much as possible to the prophylaxis of this and many other diseases."

THE TRAINING OF THE INDIAN SUBORDINATE MEDICAL SERVICE.

SOME 250 students of the Punjab Medical College at Lahore recently waited on the Inspector for Civil Hospitals to represent certain grievances. They complain that certain of the native professors are arbitrary and abusive, and desire the right of direct appeal to the Principal. They also represent that their books and appliances are obsolete, and begged that the lectures should be delivered in English, as all have passed a sufficient test in English at the Entrance Examination.

The unanimity of the students in this case makes it probable that the above incident is no mere ebullition of the factiousness to which the native student is some-

times prone, more especially as there can be no doubt that they have grave and genuine grounds for their dissatisfaction. As to the merits of their complaints against their native lecturers we have no means of judging, and, in any case, they affect the qualifications of individuals only and not the general question of the system of management of the vernacular medical schools; but the plea of the students is really for European governance and teaching, and is a very remarkable instance of the genuine preference of the Indian for English rule. The young educated Indian is, very naturally, apt to inveigh against his rulers as invaders and oppressors, but where his personal interests are concerned he will generally be found to prefer English professors and judges to his own countrymen. Personally, we think this distrust is generally quite unmerited, but it is possible that the native best knows his own business, and there can be no doubt that in this particular case the students' strictures on the schools and their appliances are quite justifiable, and especially in the matter of available medical literature. The vernacular medical student is so poor that the publication of books to meet his requirements cannot possibly be expected to be a paying transaction, and hence most of those available are practically obsolete *rechauffés* of English text-books, designed to meet the requirements of European students of a past generation. It must be remembered that text-books intended for the use of candidates for full medical qualifications are quite unsuited for the purpose of the vernacular student, as they are over-laden with too much detail to be fitted for the use of men who have but a limited time at their disposal; and hence mere translations of even the best modern text-books, however faithful, will in no way meet the special requirements of the case. To be really suitable, special text-books must be compiled in a more or less "semi-popular" style, and but little writing of the sort has, as yet, been attempted.

As already indicated in our article on "The Problem of Medical Aid in Semi-civilized Countries," we should be the last to propose to convert our Hospital Assistant class into fully qualified practitioners, but are, nevertheless, convinced that such instruction as they are given should be the best available, and that greater ability is required of lecturers who have to teach men less educated than themselves, than of those who have to deal with their own intellectual equals.

Further, it can scarcely be denied that the "Vernacular Medical Schools" are conducted by the Indian Government in far too niggardly a spirit.

The only even nominal European official is the "Principal," but as this official, as Civil surgeon of a great city, has already a very fair job for any two ordinary men on his shoulders, the time he can possibly devote to the school must be so small as to make him little less than an ornamental figurehead.

Under these circumstances the Indian "Superintendents" must needs be the real rulers of the students, and the result must be that they have power without responsibility, while the Principal is responsible, without being able, for want of time, to exercise any real power. In view of the large number of students attending the classes, and the economic importance of the service to the Indian Empire, the mere description of the present plan of management is a sufficient condemnation. It must not be supposed that we are advocating the entire substitution of European for native lecturers, as these are already far too few to deal properly with the subjects taught; but the teaching staff should be strengthened by the addition of at least two European officers, who should give their entire time to the work, and should be men not too senior to be in recent touch with the latest developments of medical science, and not too junior to possess a thorough knowledge of the vernacular; for though many of the students are fair English scholars, it may be doubted if the majority have a sufficient knowledge of our language to benefit fully by instruction conveyed through it. In making such a recommendation we wish to convey no idea derogatory to the native lecturers, most of whom are able men and most capable practitioners; but they are necessarily rather senior men before their capabilities are discovered, and through no fault of their own, they have lacked all opportunity of post-graduate study, so that the adoption of our suggestion could hardly fail to revolutionise the rather obsolete methods of teaching now in use.

To obtain suitable text-books a substantial reward should be offered by Government for the copyright of the best work for the purpose in each subject in English dress, and the selected text-books should be translated into the vernaculars by a mixed staff of English and Indian medical men.

The schools, too, badly lack apparatus and appliances for illustrating teaching, and these should be supplied.

It can surely not be said that the reforms suggested are either sweeping or costly, and it can hardly be maintained that they would fail to enormously increase the efficiency of the vernacular schools, and the invaluable service which is trained therein. Meanwhile, however, we cannot but think that the students are perfectly justified in indulging in what our Indian medical contemporary elegantly denominates as "grousing."

SERUM-THERAPY OF PLAGUE IN INDIA.[1]

Lieut.-Colonel W. B. Bannerman, the Director, Plague Research Laboratory, Bombay, in his comprehensive and excellent introduction to the "Scientific Memoirs," No. 20, new series, dealing with serum-therapy of plague in India, states that "In view of the somewhat discouraging results obtained among hospital patients in India, it seems necessary to commence anew the study of the serum-therapy of plague."

Anyone who has carefully read the memoirs in question must agree with Lieut.-Colonel Bannerman. That there are indications that the treatment of plague by serum is a step in the right direction there can be no doubt; but that the various sera to hand are administered at times or in doses sufficient to cope with the malady is scarcely apparent.

Lustig's serum.—Haffkine, W. M., contributes a

[1] "Scientific Memoirs," by Officers of the Medical and Sanitary Departments of the Government of India. Calcutta, 1905. New Series, No. 20.

report on a series of 484 cases of plague treated with Lustig's anti-plague serum. The general result was as follows: Among the 484 cases treated with serum there were 55 fewer deaths than among the 484 control cases not treated with serum.

Terni's serum.—Haffkine, W. M., and Costello, C. T., report on 110 cases of plague treated with Terni's anti-plague serum. The general result was: 89 deaths among 110 cases treated with serum, compared with 90 deaths among 110 not treated with serum.

Brazil's serum.—Haffkine, W. M., and West, W. G., report on 70 cases of plague treated with Brazil's anti-plague serum. In the Modikhana Hospital amongst the serum-treated there were 17 deaths out of 20 cases (85 per cent. mortality), against 15 deaths out of 20 control cases not so treated (75 per cent. mortality). These figures show that fewer control cases died than when serum was given.

At the Maratha Hospital the serum-treated numbered 50, died 41 (82 per cent. mortality). Control cases numbered 50, died 45 (90 per cent. mortality).

Roux' serum.—West, W. G., reports on 68 cases treated by Roux' anti-plague serum. The serum treated cases showed a death-rate of 66·17 per cent.; the control cases a death-rate of 60·29 per cent, showing a difference in favour of the control cases of 5·86 per cent. The general drift of the evidence before us is, (1) that the initial effect of the introduction of any serum has the power in many instances of reducing the temperature, the pulse and the respirations. (2) That the favourable initial effect was not maintained. (3) Life would appear to be prolonged for an average of several hours. (4) Decided reduction of the mortality cannot be attributed to the treatment by serum.

DISTRIBUTION OF LIEGE EXHIBITION AWARDS.

The awards to the British Section of the recent Liége Exhibition were distributed on June 13th. The proceedings took place at the Mansion House, and the Lord Mayor, Alderman W. Vaughan-Morgan, occupied the chair.

Mr. Imre Kiralfy, the British Commissioner-General, read a report upon the exhibition, and the meeting was subsequently addressed by the Belgian Minister, Count de Ialiang, Sir Albert Rollitt, M. Edouard Seve, Sir William Holland, and the Lord Mayor. The diplomas were then presented by Count de Lalaing. A notable feature of the ceremony was the receipt by Burroughs, Wellcome and Co. of five awards of grand prix, three diplomas of honour, three gold medals and one silver medal.

"ATTI DELLA SOCIETA PER GLI STUDI DELLA MALARIA," ROME, 1904.

In this well-known yearly publication, A. Celli gives a masterly *resume* of the work on malaria accomplished in Italy during the year 1904. The epidemic of 1904 was, generally speaking, more serious than those of the preceding years. Benign tertian was predominant in the north of Italy, while in the Roman Compagna and the south of the peninsula the subtertian was the commonest form met with. According to Celli's observation in an epidemic of malaria, cases of relapse are more frequent than cases of primary infection; relapses were extremely common in the hospitals of Rome in 1904 during the months of July and August, suddenly decreasing during September, contrary to the experience of 1903, when relapses were most frequent in September and October. Primary infections were observed to be more common in July and August.

The relation between climatic factors and malaria remains obscure; in the year 1904 the end of the epidemic coincided with the end of the hot season. The economical conditions have a certain indirect influence on the prevalence of the disease; in the more prosperous provinces the use of quinine, as a preventive and curative agent, becomes more general and the cases of malaria decrease. The author gives the results obtained by the method of prophylaxis by quinine given daily in 5 to 8 grain doses. The prophylatic administration of quinine in such doses does not generally give rise to any untoward symptoms. In Celli's experience the daily administration of quinine in the doses mentioned is of greater efficacy than Koch's method of giving a large dose once in seven or ten days. The quinine prophylaxis was in 1904 applied to 52,690 persons, all of whom were much exposed to malarial infection; of these 4,262 got malarial attacks, that is to say, 8·08 per cent. in the year.

For the railway employés, the mechanical prophylaxis by means of wire, mosquito nets, &c., was used, with good results.

In addition to this most interesting report of Celli, the "Atti" contains numerous other memoirs on various subjects relating to malaria. B. Galli Valerio and Jeanne Roshag de Jongh describe their experiments on the biology of Culex and Anopheles.

Martinetti and Castellini publish the results they have obtained in their endeavour to produce a quinine compound devoid of bitter taste. Ed. and Et. Sergent report on the epidemiological studies undertaken by them in Algeria.

Other very interesting papers are by Gualdi, Casagrandi, Gaglio and Rossi, for which we refer the reader to the original publication.

Prof. Celli and the "Societa per gli studi della malaria," are to be congratulated for the splendid work accomplished in the fight against the disease which is the scourge of the Roman Compagna and of so many other parts of Italy.

LONDON SCHOOL OF TROPICAL MEDICINE.

Entertainment to the Hon. Bomanji Petit.

On June 11th the Hon. Bomanji Petit, of Bombay, to whom the London School of Tropical Medicine is so deeply indebted for a munificent donation to the funds of the Institution, was entertained at luncheon by the teaching staff and students of the School. Sir Francis Lovell the Dean of the School presided, and amongst those present were: Sir Patrick Manson, Dr. C. W. Daniels the Superintendent of the School, Dr. A. T. Stanton, the Students at the School, and Mr. P. Michelli the Secretary. A hearty welcome was

accorded to Mr. Petit, and the Dean, in proposing his health, referred to the many benefits Mr. Petit had conferred by his philanthropy on several public and scientific institutions in India, and to his generous contribution of a lac of rupees towards the funds of the London School of Tropical Medicine. By his generosity and timely help the School had been largely relieved of the heavy financial burden necessarily incurred at its foundation, and the example he had set had directly benefited the School by inducing others to contribute to this worthy institution, and so to promote the welfare of their fellow subjects in many parts of the Empire. In reference to the present position of the School, which owed its inception to the Right Hon. Joseph Chamberlain, Sir Francis stated that the teaching and appliances in the School were of the most modern character, that much remained to be done in the way of equipment of the museum and library, and in several other directions. Money is wanted for the endowment of lectureships and for research. Recently two new Chairs had been founded, one for the teaching of Protozoology and the other for Helminthology. The Colonial Office had generously helped to establish these lectureships, whereby the efficiency of the School would be greatly enhanced. The advance of tropical pathology had rendered these Chairs a necessity, and it was no less imperative that the subject of Entomology should be placed on a similar footing to Protozoology and Helminthology. When funds were available this would be done, and it was to be hoped that a generous donor would soon come forward to enable the School to attain this desirable object. Since 1899, when the School was opened, over 600 post-graduate students have passed through a course of instruction at the School. Sir Francis closed his remarks by stating the deep indebtedness of the School to the Hon. Bomanji Petit, and expressed the pleasure it had given the Seamen's Hospital Society and the London School of Tropical Medicine to be privileged to entertain Mr. Petit and the members of his family who accompanied him.

The Hon. Bomanji Petit, in his reply, testified to the satisfaction the establishment of the London School of Tropical Medicine had given in India. There were many diseases that required elucidation, but none more urgently than plague, which had caused widespread havoc in India for many years. The prevention of plague ought to be one of the foremost subjects to engage the attention of the teachers connected with the London School, for in India the people looked to the science and skill of western doctors to free them of the scourges which decimate their ranks and materially affected the progress of the country. Mr. Petit urged the members of the School to continue their good work, and to rest assured that India would not forget their labours in the cause of mankind.

We would direct special attention to the article by Dr. E. A. O. Travers and Malcolm Watson on the measures taken to abolish malaria from Klang and Port Swettenham. That these measures have been eminently successful is a matter for univeral satisfaction, and ought to stimulate similar efforts in every part of the tropics. We are glad to note that Major Ronald Ross, C.B,, F.R.S., has drawn attention to the results this article indicates in the *Times*, so that the valuable information may reach the ears of governors of colonies and others interested in the hygiene of tropical countries.

COLONIAL NURSING ASSOCIATION.

Annual Meeting.

Lord Elgin, Secretary of State for the Colonies, in addressing the Colonial Nursing Association at the Colonial Office on June 13th, congratulated the Association on the good work they had accomplished. It is now ten years ago since Mr. Chamberlain initiated the movement which resulted in the Association being founded. In many despatches to the Colonial Office the work done by the nurses sent out by the Association has been referred to as efficient and most helpful, and there seems a tendency on the part of the Colonial Office to incorporate the nurses sent out by the Association as Government employés, and to grant them the privileges of pension attaching to recognition of the kind. Lord Ampthill, when moving the adoption of the report, said funds were wanting for the advancement of the Association, and that there were few better ways of showing interest in the Empire than by providing means whereby the public servants of the Crown in distant colonies could be provided with skilled nursing when they were struck down by illness. Sir Frederick Hodgson, in seconding the adoption of the report, testified to the valuable work done by skilled nurses in the colonies with which he was acquainted.

We can add our testimony from several independent sources as to the benefits accruing to the communities in which the nurses of this Association have worked, and it is to be hoped that the members of the committee of management of the Association will in course of time associate with them in their work those who have had practical experience of nursing in tropical colonies.

AN IMPROVED METHOD OF STAINING FOR SCHÜFFNER'S DOTS, &c.

The following method has produced results so far better than any which I have seen described, that a brief note may be worth publishing; it has also given most excellent results in slides of tropical malaria taken eight months ago, the chromatin being very well stained.

After fixing with absolute alcohol, the slides are dried and at once placed in slide jars containing Giemsa's solution 1-10 to 1-15 until they are deeply, and in fact over-stained (one to three hours should be enough). They are then quickly but thoroughly washed in plenty of water—clean rain-water does not spoil the results, and while still wet, but drained, one or two drops of pure methyl alcohol are dropped on the slide held obliquely, two to three seconds is long enough, and they are at once washed in water, dried, and mounted in the usual way.

Staining with Giemsa on the slide is no good, though it is hard to say why. In a successful prepara-

tion Schüffner's dots are very brilliant, and the substance of the corpuscle is only faintly seen. Washing with methyl alcohol after drying the slide is not quite so good a method as the above, especially with old films.

Reviews.

THE ANÆSTHETIC TECHNIQUE FOR OPERATIONS ON THE NOSE AND THROAT. By A. de Prenderville. (London: H. T. Glaisher, 1906, pp. 88. Illustrated).

Medical men called up to administer an anæsthetic in cases of nose and throat trouble are apt to be anxious as to their capacity to carry out the administration in a manner satisfactory to the patient and the surgeon. The anxiety is natural and justifiable, as any lesion of the respiratory passages tends to increase the difficulty and danger of anæsthesia. In large cities expert anæsthetists, being at hand, should be employed; but in the tropics, as a rule, every medical man has to undertake the administration of anæsthetics in cases of the kind. Dr. Prenderville's book to men so situated should prove a useful and invaluable help, as anæsthesia in nose and throat operations is always fraught with anxiety, and attended by a considerable element of danger. A perusal of Dr. Prenderville's book will enable inexpert anæsthetists to go to work with a degree of confidence they were perhaps not previously possessed of.

Notes and News.

ONE of the difficulties connected with the treatment of plague in India is to convince the people of the advantages of the evacuation of premises in which one or more cases have occurred. They cling to their houses, and thus a whole family may die in rapid succession or in periods extending over weeks. The investigations of the Advisory Committee on Plague, which is pursuing its researches in India, prove beyond question that while the disease is not particularly infectious or contagious and man-to-man infections do not play any important part in spreading it, that rooms and houses in which cases have occurred among persons or rats are very infectious during an epidemic. Those who live or sleep in such places are liable to contract plague, whereas close attendance on patients in hospital or in segregation camps is seldom dangerous. Further, even after houses have been evacuated for a month or even longer, the disease clings to them, and their re-occupation is full of danger. These facts cannot be too widely made known, and they confirm opinions that were formed some time ago. Evacuation, to be effective, must be promptly carried out, and three months may be taken as the period over which it should extend.—*Pioneer Mail.*

PLAGUE INSPECTION IN BURMA.

A SERIOUS FRACAS.

A FRACAS took place in Maymyo Bazaar the other day on the occasion of the first plague inspection by Captain Simpson of certain houses lying to the east of the town, where the *garry-wallahs'* or cabmen's quarters are situated. Captain Simpson was accompanied by Mr. Kirkpatrick, sanitary inspector, and a gang of coolies, with two civil policemen for protection. It was necessary to enter a house where a suspicious case of illness had occurred, but on Captain Simpson attempting to do so the owners resisted, and in a trice a large crowd had collected, numbering two hundred men, who had evidently been in readiness for a row. They attacked the plague gang with sticks and stones, and Captain Simpson was struck with a brick and Mr. Kirkpatrick was somewhat seriously injured. The two policemen were helpless. The matter being reported, a strong body of police started at once with Mr. Murray, D.S.P., and Major Townsend, D.C., to the scene, and some twenty men were arrested and committed for trial. As a result of this all the *garrywallahs* in Maymyo went on strike. Measures are being taken which will probably bring them to their senses, but the strike will affect the Burman and native community chiefly, for these are almost the only customers of *ticca garries.—Pioneer Mail.*

HONOURS TO BRITISH RESEARCH LABORATORIES.—Although scientific research receives little encouragement in this country, it is gratifying to find that the labours of British scientists are recognised abroad. The awards to the British Section of the recent Liége Exhibition were distributed at the Mansion House on June 13th, and the following presentations were made:—Wellcome Chemical Research Laboratories, one grand prize, one diploma of honour, and two gold medals; Wellcome Physiological Research Laboratories, one grand prize, and two gold medals. Medals were also awarded to the respective directors of these institutions.

WE refrain from comment upon the tinned meat scandals, although the matter is one of vital importance to tropical residents and travellers. The "scandals" were well known to us for some years, and avoidance of all preparations derived from "meat" in any form has been urged by us in the case of invalid dietary. Fresh beef tea, freshly made meat jellies, freshly prepared scraped beef, have been advocated by all medical men, in preference to the much advertised tinned, canned, or bottled substitutes for the same. It required, however, a sensational "novel" to bring the matter home to the public, and we cannot be too thankful to the writer of "The Jungle" that the whole question of "beef-teas" should have been raised. Medical men, however, can hardly be said to be free from blame in the matter, as they are too apt to yield to the desires of their patients to try some over-advertised "meat juice" or "beef extract." Though less nutritious than ordinary egg albumen, bulk for bulk, and in no sense better or more digestible, some of these may be harmless enough, but their adoption involves heavy and needless expense on people who are often ill able to afford it; and the profession might do much to combat the evil by resolutely refusing to countenance the use of all preparations of the sort

except in the rare cases where the wholesome fresh materials are absolutely unobtainable. All medical men who desire to be ready with arguments as to the valuelessness of these much puffed articles should read Dr. Robert Hutchison's excellent pamphlet on "Patent Foods and Patent Medicines," and the booklet is so plainly written that the laity might do worse than follow their example.

By the death of Professor Schaudinn at the early age of 36, science has sustained an irreparable loss.

Rat Fleas and Plague.—An experiment made in Bombay seems to favour the belief that rat fleas convey plague. In a room in which a rat died of plague a number of rats in cages were placed; some of the cages were screened, some unscreened. The rats in the unscreened cages contracted plague, whilst the rats in the protected cages escaped.

Dr. Nuttall, F.R.S., has been appointed Reader in Hygiene at Cambridge University.

Readers of the Journal will regret to know that Lieutenant-Colonel J. E. Nicholson is about to leave England. We are thereby deprived of the valuable assistance he has rendered to the Journal for some time past.

Lahore Medical Students, owing to alleged harsh and unsympathetic treatment by their native superiors, to the number of 250, have gone "on strike." We hope soon to hear that the students' grievances have been satisfactorily settled.

Examinations for entrance into the Royal Army Medical Corps will be held on July 26th 1906. There are forty vacancies.

Examinations for entrance into the Indian Medical Service are to be held on July 9th, 1906. There are twenty vacancies.

Dr. J. L. Todd informed the African Trade Section of the Liverpool Chamber of Commerce that in the area of country in Africa infected with sleeping sickness some half a million people died of the disease during the last ten years. Sleeping sickness had spread along the trade route opened up in recent years, and as a means of combating the disease it was suggested that medical posts of inspection should be established at regular distances, so that persons suffering from the disease should be prevented from travelling to districts as yet uninfected.

Department of Health, Isthmian Canal.—Colonel Gorgas reports that during the month of April, 1906, there were no cases of yellow fever, plague, or small-pox amongst those employed on the canal; no case of plague since August, 1905, no yellow fever since December, 1905, and no small-pox during the preceding year. The general health of all sections of the community in the canal zone has much improved lately. Pneumonia was the most serious ailment. The systematic cleansing, disinfection, and destruction of mosquito breeding-places is being maintained.

Personal Notes.

Rutherford, Dr. G. J., Medical Officer of the Gold Coast Colony, has been transferred to the Medical Department of Southern Nigeria.

Indian Medical Service.

Promotions:

Lieutenant-Colonel W. Gawen King, C.I.E. (temporary Colonel) is confirmed in that rank, and in the appointment of Inspector-General Civil Hospitals, Bengal.

Retirements.

Colonel Andrew F. Dobson (Madras), Colonel Stephenson Weir (Bombay), Lieutenant Colonel J. Anderson, I.M.S.

Leave.

Captain C. Thomson, priv. leave, 6 w.
Lieutenant-Colonel J. L. Poynder, combined leave, 6 m.
Captain V. E. H. Lindesay, combined leave, 1 y. 51 d.

Postings.

Captain W. Selby, additional Visiting Charge, Budaun.
Captain C. H. Bensely to be Superintendent, Lahore Central District, and Female Jails.
Lieutenant-Colonel H. Hendley to be Civil Surgeon, Lahore; Professor Midwifery, Lahore Medical College; and Medical Officer, Government College.
Captain C. S. Lawson is confirmed Superintendent Central Jail, Ahmedabad.
Captain A. F. W. King to be Professor, Institute Medicine and Pharmacy, Grant Medical College, and Resident Surgeon St. George's Hospital, Bombay.
Captain E. H. G. Hutchinson to be Civil Surgeon, Ratnagiri.
The services of Captains Trafford, Pilkington, Laudder and Dunn, and Lieutenant Gill, have been placed at disposal of Punjab Government for plague duty.
Major A. Buchanan to be Civil Surgeon, Nagpur.
Major E. A. R. Newman officiates as Civil Surgeon, Ranchi.
Captain C. A. Lane officiates as Civil Surgeon, Bhagalpur.
Captain J. G. P. Murray acts as second Surgeon, Presidency General Hospital.
Captain H. B. Steen to be Civil Surgeon, Purnea.

Geographical Distribution of Disease.

As information arrives we publish, under this heading, the principal diseases met with in tropical and sub-tropical countries, so that those interested in the Geographical Distribution of disease may have a means of gathering information concerning the prevalent ailments in different parts of the world.

Philippines.

Opisthorchis sinensis was discovered in a Japanese patient by Dr. R. P. Strong, and reported by W. J. Mallory, on March 2, 1905, at the annual meeting of the Philippine Islands Medical Association. The parasite inhabits the bile ducts and gall bladder of man, dogs, and cats. It has been met with in the pancreas and occasionally in the duodenum. The fact that the parasite has never been previously described as occurring in the Philippines does not point to infection of the natives of the Philippines, as the patient was a Japanese, and it is well known that the *O. sinensis* is widely prevalent in Japan.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"C. R. Soc. de Biologie," T. lx., p. 160.

ON SOME NEW TRYPANOSOMES OF FRESH WATER FISHES: THEIR EVOLUTION AND METHOD OF TRANSMISSION.

Brumpt, E., describes ten new species of *Trypanosoma* and four of *Trypanoplasma*, and states that the former undergo an evolutionary stage in leeches of the genus *Hemiclepsis*, and the latter in either *Hemiclepsis* or *Pisciola*. Some species of the trypanosomes develop entirely in the stomach, others first in the stomach afterwards in the intestine, and finally the parasites are found in the sheath of the suctorial mouth; while a third category, such as *T. Danilewskyi*, develop first in the stomach and then in the mouth-sheath. The development of *T. granulosum*, sp.n., of the eel is described in greater detail. The forms found in the stomach are pear-shaped, with the centrosome near or in front of the nucleus. These multiply actively in the stomach, but the forms met with in the intestine are very elongated, resembling *Herpetomonas*, while those found in the mouth-sheath are of the trypanosome type, and the parasites with which the fish are inoculated by the leeches are always of this form.

Those developing in the stomach have the peculiarity of losing their flagella and undergoing several fissions in this form before regaining their lashes.

"Archiv für Schiffs und Tropen Hygiene," vol. x., No. 2.

PROPHYLAXIS OF MALARIA.

Celli believes (1) that the exhibition of quinine as a means of preventing malarial fever should be continued daily in doses of 6 to 9 grains (40 to 60 centigrams). (2) The addition of arsenic and iron to the quinine in chronic malaria is probably useless. (3) The best form of administering quinine is in the form of the bisulphate or hydrochlorate in sugar-coated pills. (4) Cinchonism is more apt to prevail when quinine is given at intervals of some days than when exhibited daily. (5) The tonic effect of quinine is of value in persons infected with malaria.

Although quinine-taking is a valuable prophylaxis, it should never be allowed to interfere with the sanitary measures calculated to eradicate the Anopheles from the malaria-infected area. Whilst new ground is being opened up, and until sanitary measures are fully established, there can be no doubt quinine is the most efficient of all prophylatic measures.

"Wien Med. Wochenschrift," October, 1905.

THE TREATMENT OF DYSENTERY.

Kraus and Dörr have come to the conclusion that the *Bacillus dysenteriæ* are not identical. From Shiga's bacillus a soluble toxin has been isolated, and the type of dysentery it causes is that of a local bowel infection where the toxins are elaborated, resembling the action of the diphtheria bacillus. No toxin has been isolated from the bacillus of Flexner, so that the poison is intracellular, comparable to the bacilli of typhoid and cholera. Kraus and Dörr have produced an antitoxin which has proved effectual in cases of dysentery due to the *Bacillus dysenteriæ* of Shiga; 20 cc. of the antitoxin were injected subcutaneously, and the signs and symptoms of dysentery speedily subsided. The antitoxin is of no value in counteracting the intracellular poison of Flexner.

"Bulletin General de Therapeutique," November 23, 1905.

GENTIAN IN THE TREATMENT OF MALARIA.

Tauret, Dr. George, has isolated a glucoside from the fresh root of gentian, termed gentiopicrine. This drug, in doses (cachets) of from 7 to 46 grains, was administered in definite cases of malaria, some two to four hours before the probable onset of the malarial attack. As gentiopicrine in large doses acts as a purgative, it should be given with the food, or a little bismuth may be administered with it.

Beside gentiopicrine, another glucoside, gentiomarine, is met with in gentian, and the combination of these two glucosides may be exhibited as an alcoholic extract of fresh gentian root in syrup. The treatment may be required to be continued from one to three weeks.

A CASE OF TROPICAL ULCERATION INVOLVING THE NOSE, PHARYNX, AND LARYNX, WITH HISTOLOGICAL FINDINGS.

Arnold, W. F., and Fordyce, J. A., in a paper read before the American Dermatological Association in December, 1905, described a granuloma, involving the nose, pharynx and larynx, termed "tropical ulceration" of these parts. The microscopic findings excluded blastomycosis, actinomycosis, rhinoscleroma, leprosy and tubercle; syphilis and yaws were also excluded by the fact that the usual specific remedies for these diseases were ineffectual. Mycosis fungoids seemed to be negatived as a cause owing to the absence of fragmentation and the character of the infiltrate.

"Philippine Journal of Science," January, 1906.

TROPICAL ULCERATIONS OF THE SKIN.

Strong, R. P., describes tropical ulcerations of the skin, as met with in the Philippines, under three headings: (1) Cases resembling Oriental sore; the lesion is single and in the surrounding tissues Strong found "cockle shell" oval bodies, in diameter from 3 to 4 micra, resembling Leishman bodies, and met with free and within endothelial phagocytic cells. They are regarded by Strong as parasites and to be forms of blastomyces. (2) Cases in which the lesion is single, commencing as a red spot which enlarges, hardens, discharges and scabs. No protozoa were found, but a bacillus of the *Staphylococcus pyogenes aureus* native was met with. (3) Cases in which the lesion is multiple, beginning as vesicles or pustules and breaking down into ulcers.

Bacteria do not seem to act as a causative factor in this group, which may be due instead to a blastomycytic agent, although no organisms of this nature have been observed.

"Journ. Exper. Zool.," vol. ii., p. 585.

THE EVOLUTION OF THE HYPOTRICHOUS INFUSORIA.

Woodruff, L. L. This is a sequel to Calkins' remarkable study of the evolution of the Paramœcia, and has been carried out by his methods and under his direction, though the results are hardly as definite. The observations were devoted to *Oxytricha fallax*, *Plerotrichia lanceolata*, and *Gastrosyla steinii*, the culture medium being hay infusion. All three species multiplied steadily by transverse fission without conjugation, passing directly through periods where the division was less frequent, but in the end all die unless the race be rejuvenated either by conjugation or by change of medium. Like Calkins, he found that a cultivation that had become very languid revived at once to a considerable extent by substituting beef infusion for hay infusion, but a second experiment was not so successful, and the series died out in 20½ months after the very considerable figure of 860 asexual generations. The periods of depression were characterised not only by feeble multiplication and the commonness of pathological forms, but by alterations of the protoplasm, which became more and more vacuolated, the macronuclei broke up, while the micronuclei became more numerous, and lastly the ciliary apparatus atrophied. This was associated with an increase in the size of the individuals, which become smaller as the rate of multiplication accele-

rates. No inclination to conjugation was ever noted in the cultivations, and all attempts to bring this about failed.

Numerous observations were made on the action of various salts. KH_2PO_4, K_2SO_4 and KBr applied once accellerated, whilst K_2HPO_4, KCl, NACl and $MgSO_4$ retarded division. In daily doses $K_2H\ PO_4$ and KBR markedly accellerated, while KH_2PO_4 KCl and NACl strongly retarded division.

Light appeared to have no direct influence on the rate of division of *Oxytricha fallax*.

Prof. Mesnil, in Kolle and Wassermann's "Handbuch der Pathog. Mikro-organ." G. Fisher, Jena.

Nocht, B., and Mayer, Martin, on the pathogenic trypanosomes. This chapter of the above handbook gives a clear and definite picture of this important subject. Passing over the history of the subject, the authors proceed at once to define the two genera *Trypanosoma* and *Trypanoplasma*, and describe the methods of examination and the cytological and evolutionary characters of these organisms. Stress is laid on Prowazek's work on *T. Lewisii* and on Schaudinn's views on the hæmatozoa of birds, though they have not been able to include the more recent investigations of the latter authority, which have led him to considerably modify his views as to the inter-relations of the trypanosomes and the spirochætes.

In any case they should have noticed the views of Novy and McNeal, which are opposed to those of Schaudinn.

The authors adopt Koch's classification, and, although it is not usually a pathogenic organism, commence with the study of *T. Lewisii*, on account, no doubt, of the large amount of attention that has been devoted to that species.

The chapters on *nagana*, *surra*, *caderas*, *dourine*, *galziekte*, Gambian trypanosomiasis and sleeping sickness, are well written, and usually uniform and well balanced, and include a certain number of personal observations, notably on the pathogenic action of the two races of *T. Gambiense* on different animals. The analyst considers, however, that it would be more logical to place Zousfana disease beside Debat in the chapter on surra instead of including it with nagana, especially as they very justly insist on the difference between surra and nagana, based on the difference between the insects which act as vehicles of these diseases. The therapeutics of this subject are condensed into a separate chapter, and it is somewhat surprising to find no mention either of atoxyl or of the arsenic-trypanroth combination.

The non-pathogenic trypanosomes of mammals and other vertebrates are barely mentioned, nor are those which are almost undoubtedly pathogenic in fish, and which might well have formed the subject of a separate chapter. The tsetse flies are dismissed in a couple of pages, but an excellent double plate in contours somewhat compensates for this brevity. The other coloured plate gives a good idea of *T. Lewisii*, and of the various pathogenic species, and the microphotographs are equally successful.

Proceedings Royal Society, Series B., vol. lxxvi., p. 284.

THE DEVELOPMENT OF THE HERPETOMONAS OF KALA AZAR AND CACHEXIAL FEVER FROM LEISHMAN-DONOVAN BODIES.

Rogers, Major Leonard, I.M.S., who claims to have discovered flagellate forms of the *Piroplasma Donovani*, investigates the conditions most favourable to the development of these forms. He has already stated that these are best met by the employment of citrated human blood, slightly acidulated with citric acid, and it is further important that the medium should be free from bacteria, which impede the development of the parasites and bring about their degeneration. The most favourable temperature is 22° C. With Novy's medium (gelose blood) the results were negative. Under these conditions the small piroplasma forms, obtained by spleen-puncture, undergo rapid development, the course of which is clearly shown in an accompanying plate. After forty-eight hours the parasites have attained their largest dimensions, and some flagellate forms appear. The small nucleus or centrosome is now in relation with an eosinophile body which is constantly found in the subsequent flagellate forms. These latter, during subsequent days, are alone found, and are typical Herpetomonads. The centrosome is always in front of the nucleus and no trace of undulating membrane can ever be made out. Major Rogers proposes to call this the parasite of Kala Azar, and if, as thus seems possible, the Herpetomonoid forms of his cultures represent the most evolved stage of the organism, the term *P. Donovani* should sink, and *Herpetomonas Donovani* should be substituted for it.

Longitudinal division of the flagellate forms is also figured and described. The author remarks that the fact of acidity of the culture medium being favourable, tends to the probability that the intermediate host of the parasite is an insect, and he has actually obtained flagellate forms by mixing infected spleen blood with the stomach juices of a louse. Lastly, the fact that a temperature of 22° C. is most favourable to the development of the parasite explains the seasonal prevalence of the disease.

Journal of Tropical Veterinary Medicine, vol. i., p. 5.

A NEW TRYPANOSOME OF RATS.

Lingard, A.—The specimens described were found in the blood of *Mus niviventer* and *M. decumanus*, and differ from the types of *Trypanosoma Lewisii*, with which they are associated in having the hinder end so produced as to resemble a posterior flagellum, much longer than the true anterior one. The portion of the parasite behind the centrosome averages 19 μ., as against 6 μ. in Lewisii. In other respects, *e.g.*, in the forward position of the nucleus, the new species, which he names *T. longocaudense*, recalls *T. Lewisii*. The author proposes to facilitate the recognition of species by recording the length from the centrosome to the hinder extremity, that from the centrosome to the nucleus, the length of the nucleus, that from the anterior border of the nucleus to the anterior end of the body of the parasite, and the length of the flagellum; the sum of the five data giving the total length, and lastly, the greatest breadth. He gives their measurements for his new species, for *Lewisii*, *Evansi*, *equiperdum*, and for a trypanosome which he calls *Himalayanum*, found by him in the blood of cattle in the hills. This last is a long, thin species 75 m. long by 3·25 m. wide.

"C. R. Soc. Biologie," T. lx., p. 124.

A CASE OF SPIRILLOSIS IN THE HORSE, OBSERVED IN FRENCH GUINEA.

Martin, Gustav, describes a spirillum 12-15 μ long, by 0·25 μ wide, with 3-4 turns in the spiral. When observed, the horse was wasted and showed arching of the back with paresis of the hind quarters. Inoculation of other animals gave negative results. Two and a half months after, the horse was in good condition and its blood free from spirilla.

"Centralbl f. Bakter.," I., Original, T. xl., p. 405.

THE MODIFICATIONS OF THE SERUM OF INTERMEDIATE CARRIERS OF THE CHOLERA VIBRIO.

Friedberger, E. By the term intermediate carriers of cholera (cholerabazillenzwischentragern) the author refers to persons who, though to all appearance perfectly healthy, continue for some time to eliminate cholera bacilli in their stools. During the last epidemic in Germany he met with three cases of persons isolated from infected places, who, without even showing the least sign of cholera, nevertheless for periods of from three to nine days produced stools containing cholera vibrios. On testing the serum drawn from these persons it was found to have a bactericidal power 100 to 500 times above the normal; while on the other hand the agglutinating power alike for the cholera and for other vibrios was scarcely appreciable. To explain the presence of these peculiar properties in the serum of

these persons, the author assumes that they must have suffered from an infection of the intestinal mucosa, but of so mild a character as to arouse no suspicion of its existence in their minds; as in persons having normal intestinal mucous membranes, enormous quantities of microbes require to be introduced to produce such marked modification of their serum.

The observation is, of course, of great practical interest, as it explains how the infection of cholera may be introduced into new localities, at great distances, by a person showing no sign whatever of disease.

"Zeitschrift f. Hygiene," T. lii., p. 263.

THE ACTION OF "BRILLIANT GREEN" ON THE NAGANA TRYPANOSOME.

Wendelstadt, H., and Fellmer, T., are continuing their researches on the treatment of nagana with the colours of the triphenylmethane series. The authors have tested the action of this colour (sulphate of tetraethyldiparaamido triphenylcarbinol) in the same way they have already tested malachite green. Like the latter colour, but in a less degree, this green has the drawback of causing sloughing when used hypodermically, and of producing irritation and atrophy of the spleen when introduced into the peritoneal cavity.

Doses of 1 cc. of a ½ per cent. aqueous solution hypodermically, or of 1 to 2,000 to 2,500 into the peritoneum, uniformly brought about the disappearance of the *Trypanosoma Brucei* from the circulation of rats infected four days before with nagana. But the trypanosomes reappeared after six or seven days, so as to make a fresh dose necessary. Under this treatment, they succeeded in keeping a rat as long as seventy-two days, while control animals died in five to six days, but in the end the animals under treatment succumbed to poisoning with the drug, and in no case was a cure obtained.

The best plan of administration is in three successive doses of 1 cc. of ½ per cent. solution, on the fourth, sixth, and ninth day after infection. Following up Laveran's experiment of combining arsenic with trypan-red, they tried the effect of following up the three doses of the dye by a daily injection of 1 mgr. of arsenic. In three series, out of ten rats, one rat in the first series alone appears to have been cured, doses of 3 cc. of its blood failing to infect. In the second series the blood of four rats killed during the course of the treatment, was not infective in doses of 2 to 3 cc.; four others died no doubt from poisoning with the dye; one relapsed, and only one has been cured, being still alive after five months. This was the only instance of cure, other animals having been kept up to four months, but without being cured, and the authors attribute the comparatively good results obtained in this series to the fact that the treatment was commenced forty-eight hours after infection, and not as usual after three days. It is noteworthy that rats inoculated with the blood of some of the animals under treatment showed after a fortnight numbers of trypanosomes, which presented a vague outline and a generally curious appearance, and which disappeared the next day, but these rats showed no immunity two and a half months after.

A Macacus rhesus monkey was also treated; and as the first treatment with the green alone did not suffice, the combination with arsenic was adopted. After about seven months of repeated efforts the monkey is definitely cured, and it is an interesting and probably unique fact that it has since proved refractory to two successive inoculations with trypanosomes. In doses of ½ cc. the serum of this monkey causes the immediate disappearance of the trypanosomes from the blood of strongly infected rats, and is strongly agglutinating *in vitro*, while the serum of normal monkeys has no such action. A dog was also experimented on, but without much success. The rest of the memoir is occupied with a description of the changes produced in the trypanosomes under the action of the dye. A large clear vacuole appears around the centrosome, and a variety of other involution forms, which the authors compare to the Leishman-Donovan bodies, are described in the spleen, but the significance of these changes is uncertain.

"Transvaal Medical Journal," May, 1906.

ANKYLOSTOMIASIS IN TRANSVAAL MINES.

The above journal, in an editorial headed "Danger," draws attention to the prevalence of ankylostomiasis among the native miners on the Witwatersrand; the ova of the ankylostomum have also been found in specimens of underground soil. Although these facts are new, the journal remarks that it seems inexplicable that a vital matter such as the spread of ankylostomiasis should be treated with mysterious silence and inactivity. On this subject it may be remarked that the reports of medical men are, as a rule, disregarded by the community, and it requires some lay novelist or penny-a-liner in the lay Press to conjure up an alarming picture with an hysterical pen to bring the matter home to the people.

THE INCREASE OF MEDICAL MEN IN THE TRANSVAAL.

At the recent annual dinner of the Transvaal Medical Society the matter of the influx of medical men was spoken of with some concern. The accession to the ranks of medical practitioners was stated to be out of all proportion to the increase of population. The increase of contract practice and how to stem it is the problem which at present confronts the medical profession in the Transvaal, for there can be no doubt this sort of practice, once begun, is difficult to get rid of. Whilst the total earnings of the medical profession in the Transvaal have probably decreased since the pre-war days, the number of practitioners has doubled. Under these circumstances it is difficult to find a ready solution, but were the medical papers in Britain to make it widely known that the Transvaal is "over-doctored" at present, a check might be given to still further congesting the already plethoric ranks of the profession in South Africa.

"The Journal of Experimental Medicine," May 25, 1906.

THE RELATION OF TYPES OF DIARRHŒA IN CHILDREN TO STRAINS OF BACILLUS DYSENTERIÆ.

Knox, J. H. M., and Schorer, E. H., from their inquiry into this subject, found that the association of the dysentery bacillus with diarrhœa in infants is now established. After the study of 74 cases of diarrhœa in infants they found: (1) The Shiga type of bacillus present to the exclusion of other pathogenic species on aerobic plates in 4 cases. (2) The "Y" bacillus of Hiss was proved to be present in 14 cases. (3) The Flexner-Manila bacillus occurred in 3 cases. (4) Cases in which the dysentery bacillus was isolated, but not determined, numbered 3. (5) A lactose-fermenting dysentery-like organism was obtained in 2 instances. (6) Combined dysentery bacillus and streptococcal infection occurred in 11 cases. (7) Streptococci only were encountered in the pathogenic bacterial species in 6 cases. (8) A pathogenic colon bacillus was isolated in 2 cases. (9) No pathogenic organism or organism agglutinating with the patient's blood was found in 10 cases. (10) More than one bacillus was present in 13 cases. The combinations were as follows:—Group 1 and 4, 2 cases; group 1 and 2, 3 cases; group 1, 2 and 4, 2 cases; group 1, 2, 3, 4, and lactose, 1 case; group 2 and 4, 5 cases.

Bacilli dysenteriæ occurred in 73·1 per cent. of cases studied, or without the lactose-fermenting organism, which is probably not a true dysentery bacillus, 70 per cent. The character of the intestinal lesions found at autopsies were extremely various and without definite relation to the types of infecting dysentery bacilli; and it would appear that no distinction, except possibly as regards degree, can be drawn between the lesions produced by any of the given types of the dysentery bacillus.

The serious nature of the ailments from which the observations were taken may be gauged by the fact that 31 children of the 74 in question died.

"Il Policlinico," Rome, June, 1906.

THE EFFECT OF THE X-RAYS ON MALARIAL DISEASES.

"L'azione dei raggi Röntgen nell'infezione malarica." By Dr. Alberto Demarchi.

For obvious reasons it was not an easy matter to study the action of the X-rays when applied directly to the malarial parasites; for this reason Dr. Demarchi had to restrict his observations mainly to the region of the spleen, but his studies were equally directed to all three species of malarial infection, whether quartan, benign tertian, or æstivo-autumnal.

A microscopic examination of the blood was always made both before and after the application of the X-rays, as also some hours after it.

In all the cases the rays were applied daily, and at all periods of the attack of ague. No accidents had to be recorded, whether local or general, with one solitary exception when a slight erythema appeared over the irradiated region. The patients were subjected to rays with a penetration of No. 6 Benoist, and the quantity of the rays absorbed at each sitting was equal to 2 H units.

The results of Dr. Demarchi's researches may be summed as follows :—

(1) The application of X-rays over the splenic region does not affect or in any way modify the course of the malarial attack.

(2) These applications exercise no action whatever on the number, the vitality, or the normal cycle of development of the malarial parasites of whatever species they may belong to.

(3) They are not capable of causing or of accelerating a relapse.

(4) The X-rays have a manifest action on the reduction of the swelling of a spleen if chronic.

(5) These rays may possibly exercise a favourable action in preventing relapses of the infection.—(J. E. N.)

"Journal of the American Medical Association," May 12, 1906.

TREATMENT OF SNAKEBITE.

Crum, C. W. R., M.D., treats bites of the copperhead snakes by freezing the area around the bite with ethyl chloride spray; he then makes two parallel incisions almost an inch in length, through the wounds made by the fangs; the part is then soaked for a few minutes in strong permanganate of potassium solution and dressings applied wet with this solution; the edge of the dressing is raised every half hour or hour and a fresh permanganate solution poured on the wounds.

VERRUGA PERUANA.

By M. D. Eder, M.R.C.S., L.R.C.P., B.Sc.Lond.

Dr. Tamayo[1] may fairly claim to have solved this mystery of the High Andes. The disease has been known to Europeans since the sixteenth century, and, as Hirsch observes, its mortality for the white man was made manifest when it caused the death of more than one-fourth of Pizarro's small army of 700 men. In later years even greater havoc has been wrought. In 1874 a party of 40 sailors deserted from a British ship to work upon the Trans-Andean Railway; in the course of seven or eight months 30 were dead of verruga.

Hirsch gives the mortality as 6 per cent. for Indians and negroes, 12 per cent. to 16 per cent. for whites, amongst whom in epidemic form it may reach 40 per cent.

Regarding the nomenclature, the term "Carrion's disease" has been applied to the pernicious febrile form since 1885, when Daniel Carrion, a Peruvian medical student, inoculated himself in both arms with the blood taken from a verruga excrescence. He developed a severe illness on the 21*st* or 23*rd day* and died fifteen days later, *without the appearance of any eruption*. It is also known as Oroya fever, from the narrow valley of Oroya, where the disease is endemic.

I can find no one previously to Dr. Tamayo who has considered the possibility that the verruga and the severe symptoms of Carrion's disease are independent conditions, having a purely coincidental relationship. Dr. Tamayo does indeed hint at the verruga being favoured by the more serious disease, but I think this must have been an idea thrown out to lessen shock among his audience.

From my own experience I should say there is no disease in South America (and I speak from knowledge gained in three Republics) which is so frequently overlooked or wrongly diagnosed as enteric fever. In recent years malaria could be excluded, of course, by a blood examination, not always, however, for it is a frequently co-existing condition in other diseases. But a positive diagnosis of enteric is something quite different. The Widal reaction was not available in the Hinterland, away from laboratories; I should imagine that the Parke-Davis's Typhoid Agglutometer might prove of immense value to the medical man in isolated districts where laboratories and consultations are unattainable.

The possibility that Carrion's disease is enteric fever is so engrossing in itself, and so important is the question of enteric fever in the tropics, that some little attention to the current descriptions of verruga will not be without general interest.

Tamayo himself suggests that Carrion fever is a para-typhoid disease; I should be content to leave it at that, but I must draw attention to a few weak points in his paper.[2]

(1) The doses and strengths of the inoculation experiments are vaguely given as a few drops, a strong dose, &c. The author refers to a table which does not, however, accompany the articles, but as the paper was read at a medical meeting, the table may have been exhibited there. That table possibly gives the exact doses and strengths used.

(2) The differentiation from Eberth's bacillus or other members of the typhoid group is incomplete, more especially as no polysaccharide fractional differentiation is mentioned. But Tamayo states that he is still engaged on the complete differentiation of Barton's bacillus, and he promises to give the results in a later paper.

(3) The most serious omission is the incomplete description of the *post mortems*, both of the animals that died after inoculation, and of the patients who died during the course of the malady. We are told, indeed, that nothing particular was observed, and this even in cases where there had been during life abundant diarrhœa, enlarged liver and spleen, &c. The condition of the intestines is not once alluded to. I must ask readers not to conclude from this that no ulcerations of Peyer's glands were present. There is nothing to show that the intestines were examined. Positive evidence would here strengthen the case enormously, but the negative evidence must not be allowed to influence us too severely. Imperfect observations are a frequent fault of *post mortems* made in tropical South America as well as elsewhere.

A study of Dr. Tamayo's paper in conjunction with the following extracts will, I think, convince the most sceptical that Carrion's pernicious fever, Oroya fever —the severe fever of verruga—is nothing but enteric fever.

Relationship of Verruga to Yaws.—Manson [1] writes: "If difference there be in their clinical features between verruga and yaws, apparently it is more one of degree than of kind." Scheube [2] is to the same effect. "I am, therefore, inclined to the opinion that the two diseases (yaws and verruga) are nearly related, verruga being nothing more than a severe form of frambœsia or yaws, modified partly by the high altitudes of the region where it occurs and partly by being complicated with malaria."

On the other hand, Hirsch [3] denies any relationship, whilst Dr. Plehn [4] states, "verruga and frambœsia were formerly considered related diseases, but the former has nothing but a superficial resemblance with that skin disease." Jeanselme [5] is equally emphatic, "c'est à tort qu'on a voulu identifier la verruga avec le pian."

I will return to this question again.

Ætiology.—Certain waters of the endemic districts have always been locally under suspicion (aguas de verruga is the term). Dr. Plehn follows Hirsch, who quotes Dounon's experience; he and his followers drank the waters and were not affected. Plehn further

[1] *La Crónica Médica Lima*, Nos. 406 and 407, 1905. Apuntes sobre la bacteriología de la enfermedad de Carrión, por el Dr. M. O. Tamayo.

[2] Abstract, Journal of Tropical Medicine, May 15th, 1906. Page 159.

points out that people suffer from verruga who have never drunk the suspected waters.

Both statements are, of course, consistent with the view that the water is contaminated by typhoid excreta. (We remember that Dr. Klein swallowed a culture of Koch's cholera bacilli with impunity.) Some of Dounon's followers may have been immune to typhoid fever from a previous attack, nor would the water be the sole source of infection—direct contagion is common where there is no strict hygiene.

Pathological Anatomy.—The mucous membrane of the intestine is occasionally hyperæmic. *The solitary follicles and Peyer's glands are generally enlarged.* Sometimes ulcerations are discovered in the intestine as well as in the stomach. Scheube treats these as ulcerated verruga, but offers no proof; are they typhoid ulcers? All the lymphatic glands appear swollen, the mesenteric glands more especially so. The liver and spleen are enlarged. (Scheube and Plehn.)

Bacteriology.—In 1898 some growths were examined by Charles Nicolle [6], who reported that he had found a "microbe pathogène nouveau à ranger dans la catégorie des microorganismes dont le bacile de Koch est le type. Ce serait un Sclerothrix." M. Letulle and Izquierdo confirm the presence of an acid-fast bacillus.

The presence of this organism counts for little or nothing in the absence of inoculation experiments.

Dr. Barton's important paper referred to by Tamayo was read in 1898 or 1899 to the Sociedad Médica Union Fernandina of Lima. I can trace no reference to this paper, but Tamayo is sufficiently explicit. Barton was the first to isolate an organism from the blood of patients suffering from verruga.

Tamayo, working with Ugo Biffi and J. C. Gastiaburù, confirms all Barton's work in so far as it is morphological.

Dr. Odriozola [7] also refers to the presence of these micro-organisms in the blood, which grow readily at 37° C. on all media.

Jeanselme (loc. cit) suggests that the fever "qui est aujourd'hui definitivement rattachée à la verruga est une forme aiguë septicénique." Firth [8] thought that Carrion's death might have been due to septic infection.

Plehn, Jeanselme, and Firth (who seem tc be the only recent European writers on the subject to have seen any cases), scout very properly any connection between malaria and verruga.

Tschudi, in 1845, noted that death may sometimes occur at the commencement of the disease with typhoid, *i.e.*, septicæmic symptoms (quoted by Hirsch).

Firth suggested that the disease was due to a parasite worm, whose first stage is passed in the mud (he thus accepts the view of water being a factor in the causation). Plehn (loc. cit.) likewise broaches the possibility of some trypanosome infection. (Parasit welcher den trypanosomen vielleicht nahesteht.)

Immunity.—Jeanselme states that one attack confers a fairly long period of immunity.

Incubation of the Disease.—Carrion's fatal experiment established this at about twenty-one to twenty-three days (cp. enteric).

Varieties described in the Text Books.—(1) Fulminating, in which there is no eruption, most writers concurring in the opinion that death ensues before the eruption has time to appear. Naturally, there can be no proof of this.

(2) Pernicious febrile form (Fièvre grave de Carrion). This disease lasts two to six weeks, and has a high mortality.

(*a*) With eruption—which may appear at any time during the disease—sometimes just before death, or sometimes during convalescence.

(*b*) Without eruption.

In some fatal cases, however, verruga has been found in the internal organs (see list compiled from Tamayo, case 3. JOURNAL OF TROPICAL MEDICINE, May 15th, 1906, p. 160).

(3) Chronic form. This may drag on for years; and then, as Dr. Plehn [9] states with a touch of unconscious humour, these cases may still have a fatal issue. (Although no one has suggested that chronic verruga would confer immortality.)

Symptoms and Course.—I give the outlines from Plehn, with whom other writers are in general agreement.

Fever, remittent or intermittent, extending over some weeks. Hyperpyrexia has been known. In some cases fever falls below the normal some days before death (cp. the typhoid condition in enteric).

In favourable cases sleeplessness and other symptoms gradually disappear as the fever abates; appetite returns, and, except for the weakness, patient is well.

Headache and pains in the limbs during the first one or two weeks. Delirium, coma, nausea, vomiting, diarrhœa, dysenteric stools—more rarely there is constipation (see Tamayo's cases). The abdomen is tender. Liver, spleen, and mesenteric glands enlarged. Anæmia, sallow complexion, sometimes jaundice. Hypostatic pneumonia; cardiac failure.

Hæmorrhages from different organs.

Petechial eruption, which sometimes resembles purpura hæmorrhagica (cp. enteric; out of Osler's 829 cases, there were 25 with purpuric spots. Osler. Fifth edition, p. 17).

Differential Diagnosis.—It is significant that Wurtz and Thiroux [10] do not mention enteric amongst the difficulties. Their list of diseases with which verruga may be confused is (1) malaria, (2) acute hepatitis, (3) acute yellow atrophy, (4) acute miliary tuberculosis (5) pyæmia, (6) rheumatic fever.

Acute yellow atrophy is rare everywhere; rheumatic fever uncommon in tropical South America, but enteric is ubiquitous and common. Tamayo and his fellow workers have, I believe, proved that verruga peruana is a benign disease, running a chronic course, consisting essentially in the formation of granulomatous eruptions on the skin, and in the mucous membranes and organs.

The resemblance of these tumours to those of yaws is unmistakeable in the photographs (see them in Odriozola's work or Plehn's article). The main difference is that yaws is said not to occur in the internal organs. It does occur, however, on the mucous membranes of the cheeks, gums, and in the vulva (Hirsch). According to Van Leent, quoted by Hirsch, yaws is found in the internal organs, spleen, liver, &c. May not the fact of this having been doubted (see Hirsch) be due to the fact that the outcome of yaws is "always

towards a cure." Hence *post mortems* must be rare; whilst in verruga they have been relatively frequent, owing to the fatality of the frequently associated Carrion's fever.

As an objection to the identity of the latter with enteric fever, it may be said that there is in the clinical accounts an absence of the usual abdominal complications, such as perforation. This is true, although hæmorrhage from the bowels is noted, and amongst the sequelæ are given nervous affections. Possibly when the attention of Peruvian clinicians is drawn to Tamayo's suggestion, we may receive further information regarding the presence or absence of the abdominal complications.

To sum up, Carrion's pernicious fever is typhoid fever occurring in the tropics.

Verruga Peruana is yaws occurring in a district in Peru where typhoid is endemic. The two diseases are thus often found in the same subject.

The casual agent of verruga is unknown; hitherto, as was natural, research has been mainly bacteriological. It would, however, seem advisable to examine the freshly excised granulomata for spirochætæ, or, as Mr. T. P. Beddoes suggests to me, for some form of amœba.

A NOTE ON THE HABITS OF *ORNITHODOROS MOUBATA*.

(Observation of Two Gravid Females.)

By F. C. WELLMAN, M.D.

MR. R. NEWSTEAD in his paper "On the Pathogenic Ticks Concerned in the Distribution of Disease in Man, with Special Reference to the Differential Characters of *Ornithodoros moubata*" (read at the last meeting of the British Medical Association, held at Leicester)[1] states (what is true of most ticks) in his remarks on the family in general, that a fully engorged tick . . . after fecundation invariably falls from its host. *Egg laying takes place shortly afterwards, and the animal subsequently dies.*"[2] Later, however, in speaking of *O. moubata* he does not state the length of time between the feeding (and fecundation) of the tick observed by him and its egg laying (although he gives the dates on which the eggs were laid), nor how long the parent lived after ovipositing. Now *O. moubata* is (in some instances at least) an exception in this respect to other observed ticks, and what Mr. Newstead omits (rather than what he says) makes his sketch of the part of its life history discussed by him misleading. I extract from my recent report[1] to the American Society of Tropical Medicine concerning this tick the following observations which, if read in connection with Mr. Newstead's paper above mentioned, will give any one interested a much clearer idea of the matter. "Ticks were fed on the blood of a young pig. Copulation was seen in two instances, the ticks grasping each other with their legs and approximating the dorsal surfaces of their bodies. Two large impregnated females were placed in a covered glass dish in which was a handful of dust from the floor, into which the ticks immediately burrowed. They were given no food and examined frequently. *It was nearly two months (fifty-seven days) before any eggs were laid. Tick No. 2 did not begin to lay for a week after her companion had finished. Both ticks have been kept to date without food (eleven weeks since laying their eggs) and are still alive and active.*"[2] In each case the eggs were laid in batches and protected by the parent for several days. Their subsequent history—differentiation of the egg contents in about a week, the quiescent larvæ distinguishable a few days later, and the emergence of octopod nymphs on the fifteenth day—corresponds almost exactly with that given by the late Dr. Dutton and Dr. Todd, and as I have elsewhere published the same in detail from my own personal observations I shall not repeat it here. I have only referred to the matter in order to add important details which are missing from Mr. Newstead's paper as it appears in the JOURNAL. Of course, the paper in question may be but an abstract of a fuller communication including all the data which I have here supplied (I have not seen full reports of the meeting at Leicester), in which case, however, no harm will be done by again calling attention to so interesting and significant a point regarding the life history of an important disease carrier.

Bailundo, West Africa.

[2] Six months have now passed since the ticks were fed, and about four months since they deposited their eggs. One of them (the one which laid her eggs last) died three weeks ago. The other is still alive and apparently healthy.

A CLINICAL PICTURE OF RELAPSING FEVER.

By V. G. DESAI, L.M.S.

THE following history is a pen picture of five hundred cases of relapsing fever. The description of this fever is so vague in the text books that the disease can hardly be made out by the bedside. A few of the leading symptoms are not mentioned in any book. An ordinary busy practitioner has to

depend much on the signs and symptoms of a disease. He cannot go on examining the blood of every patient who comes to him. The writer felt the necessity of such an accurately described clinical history, and that is why he has taken the liberty to write the clinical story of relapsing fever. *It is mainly a tropical disease. It is frequently mistaken for plague in Bombay during the epidemics of the latter disease.*

This fever is only prevalent among the poorer classes of people; for example: butchers, clerks, &c. Such people eat very little fresh vegetables, fruits or fish. Christians living miserably get it. In all these cases it was generally found that the patients were not taking a sufficient quantity of salt with their food. Persons in similar conditions of living are attacked, and so it is thought to be contagious, but it appears not to be so at all. It occurs among people of low vitality. Tubercular persons of fair type are more prone to it. Males are attacked more than females. It generally occurs in outbreaks. Age has nothing to do with it. It occurs in well ventilated houses.

The patient comes to the doctor for pains in the body. The fever comes on without shivering and reaches its maximum height on the second or third day. The patient appears to be very much exhausted. The facial expression indicates that the patient must have been ill for at least two or three months. His conjunctivæ are yellow or a tinge of it is usually there. There is no sickly smell about him, as in cases of typhoid or pyæmia. The temperature depends on the constitution of the person; it is higher in thin and fair-skinned people. In fat and dark-skinned people it is less marked.

The skin in many cases is coloured a light yellow, while in some the colour is distinctly marked. A small-pox-like eruption is occasionally seen, but has not the shotty feel.

Respirations are increased to thirty or more. Percussion shows a little hyper-resonance. The respiratory phenomena look like that of hæmorrhage—probably due to the destruction of red blood corpuscles by the spirilla. Similar breathing is noticed in pneumonic plague.

The pulse is always rapid, about 100, but good. The heart-sounds are feeble, but not so feeble nor obscure as in plague. Percussions over the heart show that the cardiac dull area has diminished, while in plague it is increased from dilatation.

The appetite is poor. Vomiting is a rare symptom. In one case it was very marked. Vomiting of blood occurred in one case. Constipation is usually present, and if a purgative be given the stools do not smell as in typhoid. Large doses of calomel do not induce diarrhœa. The motions are dark-coloured (iron-laden stools), probably due to the destruction of red blood corpuscles. Distention of abdomen is a very rare symptom, unlike typhoid. Assimilation is very poor. The patient becomes markedly emaciated even in one week, in spite of careful nursing. The spleen is enlarged and very tender, as also the liver, but not to the extent of the spleen, and is less tender. Tenderness of spleen is prominently marked in all cases. General glandular enlargement is a rare symptom. The tongue shows irritation. It is thickly furred and moves less freely, resembling a "liver" tongue. Such a tongue is seen in cerebro-spinal disease. The tongue at once makes one suspicious of plague, but it is not so foul. It shows that the patient must have been ill for two or three months, although he may have been ill only for two or three days. It gets worse and worse in spite of treatment. By the last two days the tongue becomes small in mass, dry and leathery. The teeth become dry and sordes collect on them, and the look of the face is like that of a cadaver.

Urine is very red and of high specific gravity. Traces of bile are present, chlorides are less.

Intelligent people complain of pain in the epigastrium, while dull people say they have the pain in the abdomen. Pain in the calves is a very prominent symptom, and present in one and all cases. Pain all over the body is complained of, but it is more in the muscles and tendons than in the bones. The pain is more marked in the anterior parts of the body—with the exception of the calves—and the flexors. There is no severe pain in the head, as in typhoid fever, nor is there any pain in the back-bone and neck, as in cerebro-spinal fever. The patient does not sleep during the period, in spite of big doses of opium. He is neither delirious like a typhoid patient nor dull like a plague patient. The mental power is clear, but the calculating power of the brain is affected.

The muscular power is reduced from the commencement. He cannot even sit for any length of time, but, unlike a plague patient, he can walk straight.

In spite of treatment the patient gets worse and worse, and towards the end of the fever the typhoid state is pronounced. Suddenly, on the seventh, eighth, or ninth day the temperature falls to subnormal, either with profuse perspiration or with diarrhœa, or with vomiting of blood, or epistaxis. While the temperature is going down the patient asks for food. The jaundice remains behind for a week after the fever has fallen to subnormal. In the interval after the fever the patient seems well. He eats greedily and seems to make up for the loss of food in the week previous. He does not complain of any pain or any after effects (except jaundice). The only symptom that remains behind when the fever has left is jaundice, and especially when it has been marked. He gets good sleep. The motions become yellow. The spleen becomes small.

After five, six, or seven days the patient gets fever again with all the previous symptoms. This relapse is mild in many cases. People who develop jaundice, or who vomit blood during the first attack get the relapse in severe form. The jaundice is intensified, the secretion of urine becomes less, and more blood is vomited. The urine contains blood during the relapse. Even these cases recover splendidly provided they are not actively drugged. The people who pass blood are "bleeders" generally, or, as they say, their wounds take a long time to heal. The relapse is short, *i.e.*, it lasts for four or five days only, and the patients bear it better than the first attack. Rarely a third attack is noticed.

Out of 500 cases one case died of suppression of urine, two from exhaustion, one from meningitis, and two from heart failure.

Diagnosis.

A poor patient comes to a doctor with pains in the abdomen and calves, and with jaundice. History shows sudden accession of fever without shivering and occurrence of similar cases of fever in the neighbourhood.

This fever is not malaria, because quinine in very big doses has no effect and patients do not shiver.

It is not plague, because almost all patients recover, there are no buboes, and the fever is less.

It is not rheumatism, because the pain is in muscles and tendons, and salicylate and alkalies have no effect on its course, and there is no swelling of joints.

It is not typhoid, because the duration is only seven days; the characteristic headache and slow pulse are wanting; there is no diarrhœa. Chlorine mixture seems to do harm in this disease.

The diagnosis is very simple if microscopic examination of the blood is made.

Treatment.

The fever runs its course and defies all methods of treatment. The less active medicinal treatment you give these people the better.

Opium in pill form, pushed to produce pin-point pupil, does some good.

Quinine in 5 gr. doses keeps a check on the peculiar "air hunger" respirations. Patients getting quinine have better pulse than those taking diaphoretics. The motions are less coloured under quinine. The relapse is more marked in patients who take quinine during the first attack.

All antiseptics seem to do harm in this fever.

Diaphoretic treatment is exhausting.

Cold water baths are very beneficial. Still, under cold baths the tongue does not improve as it does in typhoid; but the "air hunger" respirations diminish. The urine is improved by baths.

Food consisting of fresh fruits, especially oranges in abundance, fresh milk, fresh mutton broth with plenty of salt, and green vegetables is the proper diet. Alcohol seems to do harm in this fever; even the worst cases recover without a drop of it.

Nothing active should be done for the jaundice. Fomenting over the liver for pain does harm Vomiting is not amenable to any treatment.

To check the relapse residence must be changed at once. Fruits, port wine and plenty of common salt help to render the relapse less severe.

THE ANATOMY OF THE BITING FLIES OF THE GENERA *STOMOXYS* AND *GLOSSINA*.

By Lieut.-Colonel G. M. Giles, I.M.S. (Rtd.).

(*Continued from p.* 202.)

The heart lies almost free in the pericardial cavity; but is, nevertheless, firmly supported by muscular bands, the alar muscles described by Prof. Minchin, but these seem to me quite distinct from the strong antero posterior muscle which forms a part of the pericardial septum, and which, to judge from his plate lxv. is the structure so named by Lowne in his book on the blow-fly.

This latter structure is well represented in both *Stomoxys* and *Glossina*, and does not appear to me to have any direct connection with the heart at all, and is certainly not the same as the structures referred to under that name by Prof. Minchin, which seem to have a much better claim to be so called. The muscle of the septum is a very well marked structure, broad in front and narrow behind, and is somewhat fan-shaped. The more internal fibres soon join with those of the opposite side under the first two chambers of the heart, while most of the rest extend the whole length of the septum, of which they form a considerable portion of the substance. The septum, is, however a very complex structure. It is lined with a distinct layer of pavement, endothelium (*vide* pl. i., fig. 12) and there are said to be pores in it, whereby the pericardium communicates with the general body cavity. Besides this there appears to me to be a delicate but perfectly regular layer of unstriated transverse fibres. Its lateral attachments to the terga are embedded in thick masses of the fat-body. The fat-body appears to correspond to the "cellular" tissue of vertebrates, and forms the packing of the organs not only about the septum but in every other waste space of the body. It is composed of enormous cells which appear to be usually multi-nucleate, but as a rule, it is not easy to distinguish the limitations of the component cells. The protoplasm (as shewn in pl. i., fig. 13), is vacuolated, the spaces, in specimens that have not been treated with solvent reagents, being occupied with a reserve store of nutriment.

Besides the structures already enumerated as entering into the formation of the pericardial septum, there are two distinct sorts of cell which have been indifferently referred to by authors as "pericardial cells." One category of these (pl. i., fig. 14) are undoubtedly nothing more than young mononuclear fat cells, their protoplasms having exactly the same structure as the cells of the fat body. The others are very different and are multipolar cells (pl. i. fig. 15), the poles of which, according to Lowne, are muscular fibres. These form a network over especially the lateral parts of the septum, and look exactly like ganglion cells, though it is not suggested that they are of that nature. In studying the literature of the subject it is well, however, to remember that either of the above forms of cell may be referred to by a writer, as the obvious discrepancies between their descriptions are otherwise very confusing.

As far as the writer can see, Lowne's theory that the dorsal vessel is a hollow muscular fibre is a quite accurate description of the thoracic aorta, as it seems to consist of a single row of long cells, the sides of which curve upwards to meet in the middle line above. The protoplasm, with the nuclei of these cells, forms a continuous thread in the middle of the ventral wall of the tube, lying in contact with the dorsal wall of the gut, while the lateral prolongations, which form the walls of the vessel, are extremely thin and delicate. The lumen of the tube is triangular with the apex dorsal and the flat base ventral, so that it fills up the interstice between the gut below and the lowest pair of great longitudinal thoracic muscles, and is padded on either side by rows of fat-cells.

The generative organs.—These in all Diptera, and in both sexes, consist essentially of a Y-shaped tube, the branches of which lead up to a tract of generative epithelium. Into the point of meeting of the arms of the Y, there enters, in each sex, a pair of accessory glands, so that it would be, perhaps, more exact to describe the agygos reproductive duct as dividing into four follicles; as morphologically it seems probable that the reproductive and their accessory glands may be of the same value. In the male these glands are usually spoken of as the vesiculæ seminalis, but the term is an entire misnomer, as they secrete a milky coagulate fluid which mixes with the semen in the common sperm duct, but never contain spermatozoa. Structurally they closely resemble the parovaria, or corresponding accessory glands of the female. In *Stomoxys*, however, the usual arrangement is considerably modified, as the paragonia only exist as separate lateral organs for a fairly short distance as a pair of diverticula and then unite to form a single tube which, for the greater part of its length, seems quite without convolution, and runs beside the ejaculatory duct to its point of union with the common sperm duct, which immediately after divides into three—the lateral branches or vasa differentia (efferentia of Lowne) looping backwards to the testes, while the median extension widens to form a rudimentary ejaculatory sac, which, however, has neither the muscular loops nor the fan-shaped sclerite which make it such a prominent organ in the blow-fly.

The ejaculatory duct is so small in comparison with the paragonium which lies beside it that it is very likely to be overlooked in dissecting, and the paragonium mistaken for it, as the latter is 0·15 mm. in diameter, while the ejaculatory duct is but 0·05. The duct, vasa differentia and ejaculatory sac are of exactly similar structure, being formed of a structureless intima, lined with conical epithelial cells, the apices of which project into the lumen so as to impart to it a ragged outline. The paragonium is a peculiar structure, as the lumen of the tube is surrounded by a trabecular structure, the interspaces of which are filled with a granular material. The trabeculæ radiate towards the lumen, and so have a superficial resemblance to columnar epithelium, but though I have stained them in various ways, and the lining of the ejaculatory duct lying close by has the nuclei of its epithelia quite distinct, I have never seen any structure in the granular substance which could be regarded as a nucleus, while the trabeculæ are distinctly nucleated, especially at their internodes. On this account I prefer to consider the granular substance as intercellular. The testes are two small bodies enclosed in a sac formed of flat, deeply pigmented epithelium. In mature insects it is almost entirely filled with spermatozoa of enormous length, but in young insects trabeculæ of father cells project into the interior, and there may be but little ripe sperm.

The stages of the spermatogenesis seem to be quite normal and have been described *ad nauseam* by many writers. All these structures are imbedded in a dense mass of fat-body, and in front lie beside the rectum. A rather complicated system of muscles come into view in the hindmost sections of a series which actuate the rather complicated external genitalia. For most of their course the ejaculatory duct and paragonium run rather above the longitudinal axis of the insect, but as they approach the hypopygium bend sharply down to the venter.

The female generative organs are quite of the usual dipterous type, each insect producing in the course of a season an immense number of large oval eggs.

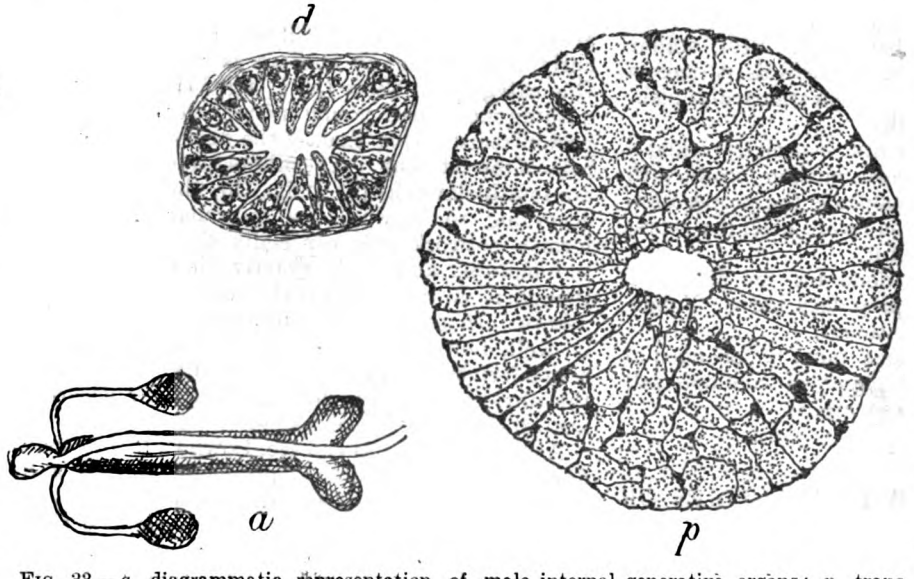

FIG. 33.—*a*, diagrammatic representation of male internal generative organs; *p*, transverse section, paragonium; and, *d*, transverse section, ductus ejaculatorius, × 400 diams.

These eggs during their development lie more or less in rows of about four ova of various stages, and it is usual to speak of these rows as "ovarioles," but the cavity containing each ovule is just as separate from the more and less developed ovules below and above it respectively, as it is from those of similar development surrounding it, and the separation in both cases consists of an open stroma of muscular fibres without any definite intima or epithelial lining, so that fundamentally their structure is the same as that of the mammalian ovary with which human anatomists are familiar. The general arrangement and relations of the ovaries may be gathered from the following figure, which includes also a diagram of the ovipositor copied from Lieut. Tulloch's paper.

The lateral oviducts, too, cannot be said to expand into a funnel-shaped receptacle receiving the ovarioles, as it seems rather a portion of the general body cavity into which the branches open, which latter receive the

ovules after the dehiscence of the muscular alveoli in which they lie, and to which they are guided by a continuity of the muscular structure of the ovary with that of the wall of the oviduct.

The smallest germ cells are multinucleate masses surrounded by a capsule of small cells. The next larger form (*b*) has two nuclei, and spring from a small celled mass on one side, while on the other the capsule is lined with large columnar epithelium, from which is developed the chorion which forms the shell of the full grown ovule (*c*). In the less mature eggs the chorion is still recognisable as a lining of flat cells (*d*) within the shell, but in those ready to pass into the oviduct it is difficult to distinguish this membrane. In ovaries in a certain stage of development before the chorion has changed into egg-shell, it is easy to mistake it for an epithelial lining of the ovariole. The eggs (*c*) are elongated ovoids having at their upper end an infolding of shell and chorion which leads to a minute canal, the microphyle, passing to the interior of the ovum to give passage to the sperm cells of the male. The stroma separating the ovarioles consists of elongated spindle cells containing each a row of nuclei. In (*e*) these muscle cells are represented in the inter spaces between three contiguous ovules. Under a high power it can be made out that the egg-shell is fibrillated, or striated vertically to its surface. Towards the end of the common oviduct there opens into it the two accessory glands (parovaria), and the ducts of the three spernothecæ.

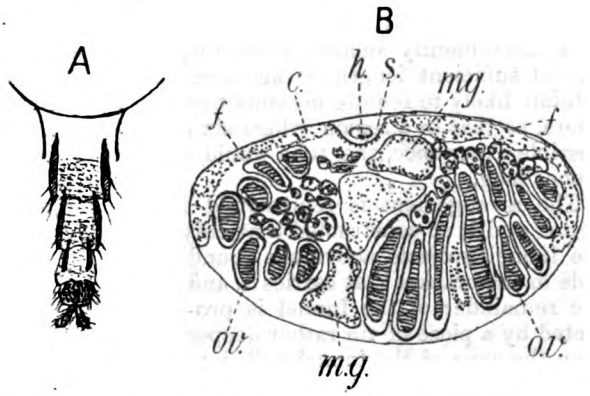

FIG. 34.—A, diagram of ovipositor, after Tulloch; B, transverse section of abdomen of gravid female; *c*, crop; *f*, fat-body; *h*, heart; *mg*, mid-gut, × 28; *ov*, ovules; *s*, pericardial septum, × 20.

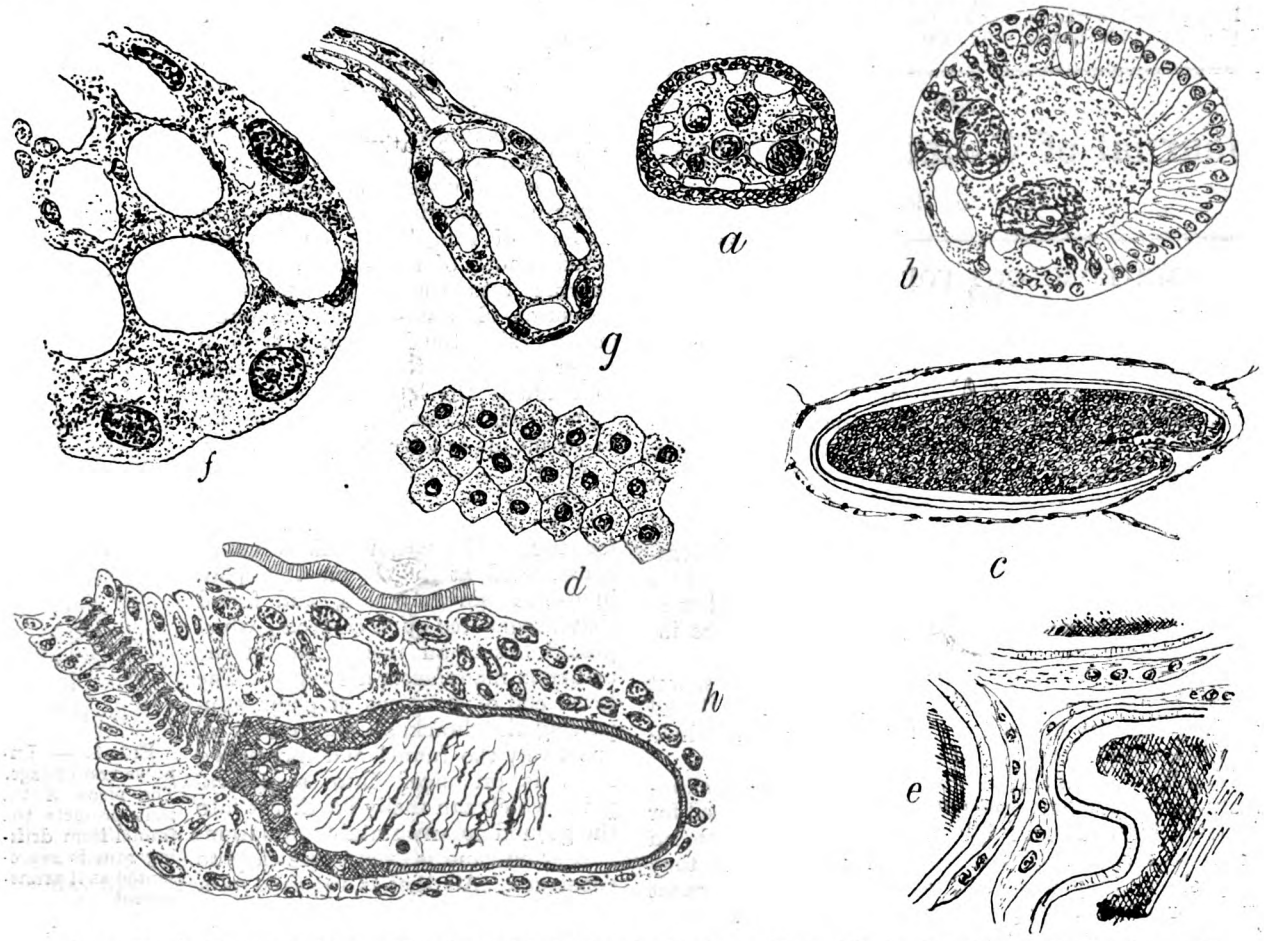

PLATE II.—*a*, Young ovariole, × 270; *b*, ovariole further developed, × 270; *c*, fully developed egg in its alveolus, × 50; *d*, portion of chorion or lining membrane of egg shell, × 270; *e*, muscular stroma separating three ovarioles, × 270; *f*, portion of parovarium, × 540; *g*, the same and its duct, × 270; *h*, section of one of the vesiculæ seminalis, × 540.

(To be continued.)

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,	5/-;
100	,, ,,	6/-;
200	,, ,,	7/6;
50	Copies beyond four up to eight pages,	8/6;
100	,, ,, ,,	11/-;
200	,, ,, ,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

JULY 16, 1906.

METEOROLOGY FOR AMATEURS.

INSISTENCE and repetition can never be fairly deprecated in a good cause, and hence we have no hesitation in returning to our contention that an immense amount of good work might be accomplished by Europeans whose business takes them to out-of-the-way parts of the world which, though fairly known from the point of view of the traveller, are as yet quite unexplored regions to the meteorologist.

The subject forms a most interesting hobby, and can be pursued at so small a cost that the consideration of expense need hardly be a bar to anyone, as a set of thermometers, a rain gauge, and a wind-vane are all that are really necessary to afford all the information essential to a preliminary survey.

A set of maximum and minimum thermometers, wet and dry bulb of each, can be got for under £2,[1] and a rain gauge for about 15s. more, so that the whole cost of a reliable outfit need not exceed £3.

Maximum and minimum thermometers, manufactured for popular use, can, however, be obtained for a few shillings, and by comparing these with an accurate instrument, and tabulating any errors they may show, they are easily available for more exact work, or a corrected paper scale may be pasted over that furnished with the instruments.

[1] A set of such instruments were supplied to the writer by Gallenhamp and Co., for £1 18s. 8d.

All that is necessary is to plunge each instrument along with a standard thermometer into water warmed to near the highest point of their scales, and to take simultaneous readings as the water cools.

A rain gauge may be improvised by utilising a large glass funnel for the purpose, and mounting it on a bracket, so that its tube discharges into a glass tube of a conveniently smaller diameter, say about $\frac{1}{5}$th, and of sufficient length to accommodate the largest rainfall likely to require measurement in twenty-four hours, so that in a region where six inches of rain is a possible experience the tube would require to be 30 inches long.

The arrangement is represented in the subjoined figure, and is so constructed that only the bare edge of the funnel projects above the round hole in the bracket that carries it, and the remainder of the funnel is protected by a piece of tin rather deeper than the cone of the funnel nailed to the edge of the bracket.

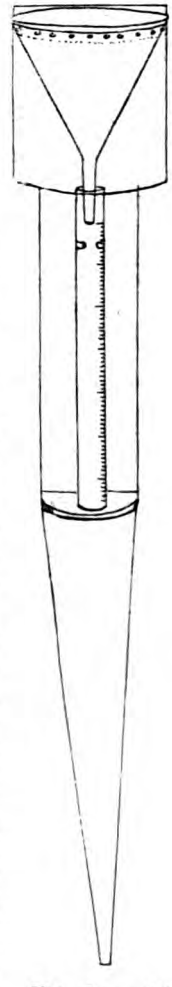

FIG. 1. — Improved rain guage. The piece of tin that protects the funnel from drifting rain is represented as if transparent.

This is necessary to prevent driving rain from striking the outside of the funnel and running down its surface into the measuring tube, which latter stands in a small hole in a lower bracket, while its upper end is held by a small brass spring clip, so that it can easily be slipped out of its supports to empty it.

Remembering the familiar formulæ that the area of a circle is πr_2, it is easy to calculate the volume of water corresponding to one-tenth of an inch of rain falling on the exposed mouth of the funnel, and by pouring into the tube successive measures of water of this amount, and marking the level on a strip of paper pasted to the tube, it is easy to graduate the latter to tenths and inches, while the cents can be put in by means of a proportional divider.

After graduation the paper should receive two or three coats of varnish, and the apparatus will then be ready for use. The writer had a gauge constructed at home on this plan in use for several years, and found that it registered quite correctly when placed beside an instrument of the orthodox manufacturer's type. The lower end of the piece of plank supporting the brackets that carry respectively the funnel and measuring tube, is prolonged into a conical point which can easily be thrust into the ground in any suitable situation.

A wind-vane is even more easy to construct. All that is required is a vertical rectangular loop of stout brass wire, the arms of which are bent to form horizontal eyes, through which is threaded a somewhat stouter wire which is fixed into the end of a pole long enough to elevate the vane above any neighbouring

obstacles, as in fig. 2. To the vertical piece of the loop is sewn a small pennon or burgee, and the points of the compass should be indicated by pegs driven into the ground around the base of the pole. In recording, it should be remembered that the burgee will point in the direction opposite that from which the wind is coming.

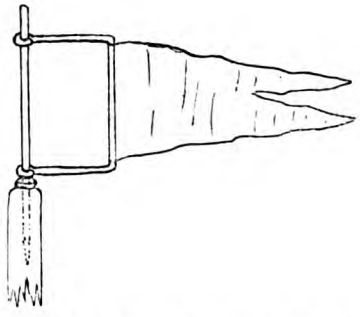

FIG. 2.—Improved wind vane mounted on a pole.

The thermometers should be mounted on a board nailed at the level of the observer's eye to the middle pole of a small mushroom-shaped thatched hut, supported on poles about 5 feet high, but quite open at the sides; and if this be made to cover a sufficient area, requires no "screen," though it is desirable to have one, especially in dusty localities, in order to protect the muslin enveloping the wet bulbs.

That no special scientific training is needed for the pursuit is shown by the fact that excellent work is done in India and other parts of the world by natives boasting of but little education, and the time that need be devoted to it is very small, as, with the system advocated in a previous article, of a single daily observation of maximum and minimum wet and dry thermometers, punctuality of observation is by no means essential, as the observation may be taken "then or thereabouts" at any convenient time of the day.

We would commend these brief notes on this subject especially to the graduates of the Livingstone College, for no body of men penetrate further beyond the bounds of civilisation; and being usually fairly stationary, they are better situated for work of the sort than are Government officials, who are usually moved too frequently from place to place to make continuous observation possible; but commercial men are sometimes equally well placed, and would, we venture to think, find an interesting relaxation from the worries of trade in wild parts of the world, by contributing to our scientific knowledge of their places of residence on this highly important subject.

LIVINGSTONE COLLEGE.

COMMEMORATION day was celebrated by a meeting in the grounds of Livingstone College, on Thursday, May 31st, Mr J. A. Simon, M.P., in the chair.

The Principal, Dr. C. F. Harford, read a brief statement with reference to the progress of the College.

In the course of his remarks, Mr. Simon said: We are, unfortunately, in this country, at this moment in a controversy about some branches of education—a subject beyond all doubt controversial, and it is therefore a great satisfaction—I hope I may say to all of us—to find that in coming here we meet, not only on common ground in the sense that we are in the spacious grounds belonging to this place, but we meet on the common ground of a common belief in the worthiness of the object, and the excellence of the method by which that object is being carried out in this place. I am sure it is a satisfaction to feel that there are still some important matters of educational life on which we can all agree.

As I understand it, this place does not claim to turn out medical missionaries, but it holds that no man or woman can serve in that high and noble office unless he or she has a knowledge of things medical such as make a part of a good education in those who are determined to learn what they should know. It seems an extraordinary thing that a man or woman, though this institution is as yet confined to men, that a man or a woman who is prepared to devote his or her life to this high calling, with no thought of drawing back in the face of danger, should go out to places, far away it may be from medical aid and from protections from disease, without such protection as a place of this kind can afford. It strikes one as startling that, as we have been told by the Principal just now, though this place has been doing its work well for many years, the great service which it could do to a large body of men and women going to the mission field is not taken advantage of by the great missionary societies to the extent one would expect. As I understand it, the people who come to this place come here primarily in order to learn how to protect their own lives and the lives of those nearest and dearest to them in the work they have undertaken, and the man who does not do that is as bad as the man who does not insure his life when he is going to be married.

I feel certain I am expressing what is in the mind of you all when I say that work such as is done here is work in which we may claim Livingstone's spirit is amongst us, and in commemorating on this day the good work of Livingstone College during the past year we are preserving and maintaining the tradition which that good man and that well-trained doctor, combined with such magnificent effect and example for all time in Africa.

Mr. James Cantlie, F.R.C.S., said: It is now thirteen years since Livingstone College was founded, and some 250 students have passed through its portals during these years, and gone into the mission field better equipped for their work than they otherwise would have been. Alas, only 250 students in thirteen years; and when we consider how many thousands of missionaries have been sent out from this country, it is evident that only a handful have been trained here. We all admire missionaries, we all esteem the man who has devoted his life to the cause of Christianity, and his efforts, it is hoped, will go on as long as our race retains its virility. The missionary takes his life in his hand when he goes forth to do his work, and comes back, perhaps, with his health shattered, or perhaps he dies at his post. For the missionary to die for Christianity is a noble end, but there is still a nobler aim—he might live for Christianity, and this College exists for the purpose of

teaching men how to live for Christianity. The work which is carried on at Livingstone College I think most of you know, it is not you who have to be told, it is the stranger without the gates. I feel rather in the position of a clergyman lecturing his congregation to be regular in their attendance at church and to be liberal in their giving; it is not to them he ought to talk about not coming to church, it is the people who do not go to church he should upbraid and remonstrate with for their niggardliness in giving. The work that is being done at Livingstone College is this: Missionaries who have gone through a course of theology for three or four years come to this College for nine months—they often come for a much shorter time—but some come for nine months, and they come to get instruction in elementary medicine, surgery, and hygiene. It really should be called by a term which is familiar to you all, "first aid" in medicine, surgery, and hygiene You are all familar, or ought to be, with how to render first aid to the injured; many of you have, no doubt, been through the St. John Ambulance first aid course. What were you taught? You were taught elementary anatomy and surgery. Some say you were taught a little knowledge, and a little knowledge is said to be a dangerous thing, but the instruction you were given was complete and exhaustive of its kind. It is a distinct branch of surgery and medicine, and therefore do not go away with the idea it only teaches you "a little knowledge," for it completely fulfils its purpose. A course of the kind would not be of direct use to you were you required to render first aid to persons suffering from disease in the tropics. Here in Britain, in our factories and workshops we find accidents are part and parcel of our daily life; street accidents occur every day. When one goes to the tropics, one finds that there are, in many places, no horses, no vehicles—if you go to South China, for instance, there are no railways, no factories, no horse vehicles, everything is carried on men's shoulders, so that there are no "accidents" such as we meet with here, and therefore it is not sufficient to be trained in merely "first aid" work which we require at home; it is not the kind of first aid that is essential there. What is required of a missionary in warm climates is to know how to deal with the sudden onset of diseases, which destroy life almost as suddenly as a railway engine may in this country. The disease comes suddenly, its course is short, and the patient may die, it may be, in a few hours. It is to teach men how to render first aid in some of the terrible maladies of the tropics that is the aim and object of Livingstone College, and it is necessary for missionaries to know something of this branch of medicine. Most clearly is it necessary, for the missionary is often looked upon by the natives as a "medicine" man, the reason being that most of the white men who first appeared as missionaries had a knowledge of medicine. Livingstone is responsible for that in Africa; his reputation as a medical man was great, and when the people saw him they knew he was capable and willing to administer relief to the suffering. Now when we send out our missionary he is looked upon as one who knows something of medicine, in the first place, from the very fact that he is a white man; and in the second place, seeing also that he is a learned man and religious, he is believed to possess the attributes all natives are accustomed to associate with religious teachers, namely, the power of healing.

What is Required of the Missionary.

A hundred years ago the priest or minister in this country was sought after by people in illness, and it was frequently part and parcel of the work of the clergy to administer to the body as well as to the soul. The same idea prevails throughout the length and breadth of Asia, Africa, and many parts of America today; the missionary is looked upon as a "medicine" man, and therefore how very necessary it is that the missionary should have a knowledge of the healing art. In the earliest days of Christianity we know the part, the vital part, the cure of disease played, and amongst the more primitive peoples of the world today the same part is expected of us. Any one familiar with the terrible epidemics which afflict humanity in tropical countries, with the suddeness of the attack and the fatal nature of many of the diseases, can well understand the desire of the natives to be saved and protected from the virulence of their scourges. This prayer of the natives for relief from suffering and from the illnesses which at times almost annihilate their tribes is a natural, a human cry, and it becomes us to treat it humanely. To these plague-stricken peoples we send in our charity missionaries; men and women anxious and willing to devote their whole time and even their lives to benefit the souls of our unenlightened fellow-beings. A noble object, and one worthy of our support, but there are means by which this excellent work can be more efficiently carried out than it is at present, and it is to provide these means that Livingstone College was called into being. Health is the handmaid of religion, and the Saxon word "heilig," which we translate "healthy," might be as correctly transcribed "holiness." The missionary sent out with no medical training is not to be envied. He may find the people around him dying of ailments which, for lack of even elementary knowledge, he can do nothing to alleviate. He can have, owing to want of instruction, no confidence in himself, and therefore cannot inspire confidence in others. The effect of such a position upon the mind or conscience of the missionary it is not pleasant to contemplate; in the name of common humanity he does his best, but his best is unskilled labour, because he is untrained, and the situation comes home to him with heartfelt regrets that he was sent out, or, that he elected to come out from home, ignorant of even the elements of medicine or surgery. Who is to blame if the missionary is sent out thus imperfectly equipped? Not the young man or woman who in the enthusiasm for the teaching of Christianity volunteered for the foreign field. The societies to whom we entrust our mission work are willing to take advantage of the enthusiasm of these young men and women, and all too frequently send them out imperfectly equipped, send them to their death in many cases because their religious fervour was not tempered with practical wisdom. The recruiting ground for missionaries is not illimitable; we are drawing upon our population in many directions for the sake of empire, and with the advance of time and opportunity more and more mis-

sionaries will be required for mission work; it behoves us, therefore, to conserve our voluntary workers in the good cause, and to see to it that their lives are not needlessly thrown away.

"Do the Missionary Societies fulfil their Duties?"
